THE PRACTITIONER'S ENCYCLOPÆDIA

OF

MEDICAL TREATMENT

PUBLISHED BY THE JOINT COMMITTEE OF
HENRY FROWDE AND HODDER & STOUGHTON
AT THE OXFORD PRESS WAREHOUSE, FALCON SQUARE
LONDON, E.C.

PRINTED IN GREAT BRITAIN BY RICHARD CLAY AND SONS, LIMITED, BRUNSWICK STREET,
STAMFORD STREET, LONDON; AND BUNGAY, SUFFOLK.

THE PRACTITIONER'S ENCYCLOPÆDIA OF MEDICAL TREATMENT

PART I: METHODS OF TREATMENT
PART II: AGENTS IN TREATMENT

EDITED BY

W. LANGDON BROWN, M.D., F.R.C.P.

ASSISTANT PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL AND PHYSICIAN TO THE METROPOLITAN HOSPITAL

AND

J. KEOGH MURPHY, M.C., F.R.C.S.

SURGEON TO THE MILLER GENERAL HOSPITAL FOR SOUTH-EAST LONDON AND TO PADDINGTON GREEN CHILDREN'S HOSPITAL

WITH AN INTRODUCTION BY

SIR THOMAS CLIFFORD ALLBUTT

K.C.B., M.D., F.R.S.

LONDON

HENRY FROWDE
OXFORD UNIVERSITY PRESS

HODDER & STOUGHTON
WARWICK SQUARE, E.C.

1915

DEDICATED TO

SIR WILLIAM OSLER, BT., M.D., F.R.S.,

REGIUS PROFESSOR OF PHYSIC IN THE

UNIVERSITY OF OXFORD

AND TO

SIR THOMAS CLIFFORD ALLBUTT, K.C.B, M.D., F.R.S.,

REGIUS PROFESSOR OF PHYSIC IN THE

UNIVERSITY OF CAMBRIDGE

IN GRATEFUL REMEMBRANCE OF MUCH KINDNESS

EXTENDED OVER MANY YEARS

PREFACE

It is impossible to overrate the importance of Treatment in the Practitioner's art, and it has appeared to us that, despite the many excellent works on Treatment that have already appeared, there is still need for a *Practitioner's Encyclopædia of Medical Treatment* on the lines adopted by the contributors to this work.

It has been our endeavour to produce a compact single volume for the Practitioner, up-to-date and not of inordinate size or cost, written throughout by men of wide understanding and experience.

We have divided the work into two parts : (1) Methods of Treatment ; (2) Agents in Treatment. In the first part, certain general forms of treatment are dealt with and then the treatment for the various disorders is arranged in a systematic manner. We have excluded details of surgical operative measures and have dealt only with the indications for such measures and the general principles of the treatment of surgical cases and of acute surgical conditions.

In the second part will be found particulars of the action and use of different drugs, which are arranged in classes. This part of the work is not in any sense a catalogue of drugs or a list of prescriptions, but rather a guide to the practitioner for the principles and methods of medical treatment.

The opinions expressed as to the value of various drugs are in every case the result of the personal experience of the writer of the article only.

We desire to express our grateful thanks to Sir Thomas Clifford Allbutt, Regius Professor of Physic in the University of Cambridge, our master and friend for many years, for the Introduction to the work. To Dr. W. J. Dilling we are indebted for assistance in the preparation of Part II.

1915

W. LANGDON BROWN.
J. KEOGH MURPHY.

CONTENTS

PART I

METHODS OF TREATMENT

TREATMENT OF THE INTOXICATIONS

TREATMENT OF DISEASES OF METABOLISM

TREATMENT OF DISEASES OF THE RESPIRATORY SYSTEM

CONTENTS

PAGE

TREATMENT OF DISEASES OF THE CIRCULATORY SYSTEM

TREATMENT OF DISEASES OF THE BLOOD AND BLOOD-FORMING GLANDS

TREATMENT OF DISEASES OF THE ALIMENTARY SYSTEM

TREATMENT OF DISEASES OF THE EXCRETORY SYSTEM

TREATMENT OF DISEASES OF THE DUCTLESS GLANDS

TREATMENT OF DISEASES OF THE BONES AND JOINTS

TREATMENT OF DISEASES OF THE MUSCLES AND CONNECTIVE TISSUES

TREATMENT OF DISEASES OF THE VASOMOTOR SYSTEM AND TROPHIC DISORDERS

TREATMENT OF DISEASES OF THE SKIN

CONTENTS

TREATMENT OF DISEASES OF THE NERVOUS SYSTEM

General and Functional Diseases of the Nervous System—

Acute Infective Diseases of the Nervous System—

Syphilitic Diseases of the Nervous System—

Diseases of the Brain—

Diseases of the Spinal Medulla

APPENDIX

KEY TO CONTRIBUTORS' NAMES

A. D. R.—A. D. Reid, M.R.C.S., L.R.C.P., Medical Officer in Charge of the Electrical Department, St. Thomas's Hospital.

A. E. B.—A. E. Barclay, M.A., M.D. (Cantab.), Medical Officer to the X-Ray Department of the Manchester Royal Infirmary.

A. E. G.—A. E. Gow, M.D., M.R.C.P., Medical Registrar, St. Bartholomew's Hospital; Assistant Physician, Queen's Hospital for Children.

A. E. S.—A. E. Stansfeld, M.D., M.R.C.P., Assistant Physician to the Metropolitan Hospital; Senior Demonstrator of Pathology, St. Bartholomew's Hospital.

A. F. H.—A. F. Hertz, M.D., F.R.C.P., Assistant Physician to Guy's Hospital.

A. G. G.—A. G. Gibson, M.D., F.R.C.P., Demonstrator of Pathology in the University of Oxford.

A. J. C.—A. J. Clark, M.D., M.R.C.P., Lecturer on Pharmacology and Therapeutics, Guy's Hospital.

A. J. J.-B.—A. J. Jex-Blake, M.D., F.R C.P., Assistant Physician to St. George's Hospital, and to the Brompton Hospital for Consumption.

A. M. G.—A. M. Gossage, M.D., F.R.C.P., Physician to Westminister Hospital, and to the East London Hospital for Children.

A. R. J.—A. R. Jordan, M.D., F.R.C.S., Pharmacological Laboratory, Cambridge.

A. R. S.—A. Rendle Short, M.D., F.R.C.S., Assistant Surgeon, Royal Infirmary, Bristol.

A. S. W.—A. S. Woodwark, M.D., M.R.C.P., Physician to the Miller General Hospital, Medical Registrar and Teacher in Medicine to King's College Hospital.

A. W.—Arthur Whitfield, M.D., F.R.C.P., Physician to the Skin Department, King's College Hospital; and Professor of Dermatology, King's College, London.

C. E. L.—C. E. Lakin, M.D., M.R.C.P., Assistant Physician to Middlesex Hospital.

C. H.—Cecil Hughes, M.B., M.R.C.S., Assistant Anæsthetist to the Westminster Hospital and to Paddington Green Children's Hospital.

C. M. H. H.—C. M. Hinds Howell, M.D., F.R.C.P., Physician, Great Northern Hospital; Assistant Physician to the National Hospital, Queen Square; and Medical Registrar, St. Bartholomew's Hospital.

C. R.—Clive Riviere, M.D., F.R.C.P., Physician to Out-Patients, City of London Hospital for Diseases of the Chest, Victoria Park; and Physician to the East London Hospital for Children, Shadwell.

D. C.—Douglas Cow, M.D. (Cantab.), Beit Memorial Research Fellow.

D. M. M.—David M. Macdonald, M.D., F.R.C.P. (Ed.), Medical Officer of Health, Leven, Fife.

E. C.—Edmund Cautley, M.D., F.R.C.P., Senior Physician to the Belgrave Hospital for Children, and to the Metropolitan Hospital.

E. D. M.—E. D. Macnamara, M.D., F.R.C.P., Physician for Mental Disorders, Charing Cross Hospital; Lecturer on Psychol. Medicine, Charing Cross Hospital; Physician, West End Hospital for Nervous Diseases.

E. M.—E. Mellanby, M.D. (Cantab.), Beit Memorial Research Fellow; Lecturer on Physiology to St. Thomas's Hospital.

E. M. C.—Edred M. Corner, M.C. (Cantab.), F.R.C.S., Surgeon to the Hospital for Sick Children, Great Ormond Street; Assistant Surgeon to St. Thomas's Hospital.

F. C. M.—F. Craven Moore, M.D., F.R.C.P., Assistant Physician to the Royal Infirmary, Manchester; and Lecturer in Medicine, Victoria University.

F. E. B.—F. E. Batten, M.D., F.R.C.P., Physician to the Hospital for Sick Children, Great Ormond Street; Assistant Physician to the National Hospital, Queen Square.

F. E. H.—F. E. Hare, M.D., Medical Superintendent to the Norwood Sanatorium.

F. F. B.—F. F. Burghard, M.S., F.R.C.S., Surgeon to King's College Hospital.

F. J. P.—F. J. Poynton, M.D., F.R.C.P., Physician to Out-Patients and Physician in Charge of the Children's Department University College Hospital; Physician in Charge of Out-Patients, Hospital for Sick Children, Great Ormond Street.

F. K.—Frank Kidd, F.R.C.S., Assistant Surgeon, London Hospital.

F. M. S.—F. M. Sandwith, M.D., F.R.C.P., Lecturer on Tropical Diseases, St. Thomas's Hospital, and to the London School of Tropical Medicine; and Physician to Out-Patients, Seamen's Hospital.

F. R.—Frederick Ransom, M.D., Lecturer on Pharmacology to the Women's School of Medicine, London.

KEY TO CONTRIBUTORS' NAMES

F. St. J. S.—F. St. J. Steadman, M.R.C.S., L.R.C.P., Dental Surgeon to the West London Hospital, and to the Belgrave Hospital for Children; and Assistant Surgeon to the Royal Dental Hospital.

F. S. L.—F. S. Langmead, M.D., M.R.C.P., Assistant Physician to St. Mary's Hospital and to the Hospital for Sick Children, Great Ormond Street.

F. W. P.—F. W. Price, M.D., M.R.C.P., Physician to the Great Northern Hospital; and late Physician to Mount Vernon Hospital.

G. A. S.—G. A. Sutherland, M.D., F.R.C.P., Physician, Paddington Green Children's Hospital, and to the Hampstead Hospital.

G. C. L.—G. C. Low, M.A., M.D., Assistant Physician Seamen's Hospital; Lecturer to the London School of Tropical Medicine; and Lecturer on Parasitology and Medical Entomology, King's College.

G. R. M.—The late G. R. Mines, M.A., Fellow of Sidney Sussex College, Cambridge; Professor of Physiology, Toronto.

H. C. M.—Hugh Crichton Miller, M.A., M.D.

H. D.—Haldin Davis, F.R.C.S., M.R.C.P., Physician to the Skin Department, Paddington Green Children's Hospital; Chief Assistant to Skin Department, St. Bartholomew's Hospital; Physician to the Hospital for Diseases of the Skin, Blackfriars.

H. E. W.—H. E. Wingfield, M.D., Consulting Physician, Royal Hants County Hospital.

H. G.—Hastings Gilford, F.R.C.S., Consulting Surgeon, Reading Dispensary and Kingwood Sanatorium.

H. G. A.—H. G. Adamson, M.D., F.R.C.P., Physician to the Skin Department, St. Bartholomew's Hospital.

H. H. D.—H. H. Dale, M.D., F.R.S., Director of Pharmacology and Chemotherapy, under the Medical Research Committee, National Health Insurance.

H. J. G.—H. J. Gauvain, M.A., B.C., Medical Superintendent, Lord Mayor Treloar's Cripple Home, Alton, Hants.

H. L. T.—H. L. Tidy, M.D., M.R.C.P., Assistant Physician, Great Northern Hospital.

H. P.—Harold Pritchard, M.D., M.R.C.P., Physician to the West London Hospital, and to the Miller General Hospital.

J. A. G.—J. A. Gunn, M.D., Reader in Pharmacology, University of Oxford.

J. A. N.—J. A. Nixon, M.B., F.R.C.P., Physician to the Royal Infirmary, Bristol; Dean of the Faculty of Medicine of the Bristol University.

J. B.—J. Bernacki, M.D., C.M., Superintendent, Plaistow and Dagenham Hospitals.

J. C.—James Collier, M.D., F.R.C.P., Physician and Lecturer in Medicine, St. George's Hospital; and Physician in Charge of Out-Patients, National Hospital, Queen Square.

J. C. B.—J. C. Briscoe, M.D., F.R.C.P., Assistant Physician to King's College Hospital, and to the Evelina Hospital for Children.

J. C. K.—J. Cade Kneale, M.B., Lecturer on Materia Medica and Pharmacology, Birmingham University.

J. D. B.—J. D. Barris, M.B., F.R.C.S., Assistant Physician-Accoucheur, St. Bartholomew's Hospital.

J. E. R. McD.—J. E. R. McDonagh, F.R.C.S., Surgeon to Out-patients, London Lock Hospitals.

J. H. S.—J. H. Sequeira, M.D., F.R.C.P., F.R.C.S., Physician to the Skin Department and Lecturer on Dermatology at the London Hospital.

J. K. M.—J. Keogh Murphy, M.C. (Cantab.), F.R.C.S., Surgeon to the Miller General Hospital for South-East London, and to Paddington Green Children's Hospital.

J. M. F. B.—J. M. Fortescue-Brickdale, M.D., Senior Assistant Physician, Bristol Royal Infirmary; Clinical Lecturer, and Lecturer of the Public Health Laboratory, University of Bristol.

L. E. H.—Leonard E. Hill, M.B., F.R.S., Director of the Department of Applied Physiology and Hygiene, National Health Insurance Medical Research Committee.

L. M.—Leonard Mark, M.D.

L. R.—Leslie Roberts, M.D., Dermatologist to the Royal Infirmary, Liverpool; and Lecturer in Dermatology, University of Liverpool.

L. R.—Sir Leonard Rogers, Lieut.-Col., I.M.S., F.R.C.S., F.R.C.P., Professor of Pathology, Medical College, Calcutta.

L. W.—Leonard Williams, M.D., M.R.C.P., Physician to the Metropolitan Hospital, and to the French Hospital.

M. C.—Maurice Craig, M.D., F.R.C.P., Physician for and Lecturer on Mental Diseases, Guy's Hospital.

M. G. F.—Michael G. Foster, M.D., M.R.C.P., Physician to the Home for Ladies, San Remo.

M. H. G.—M. H. Gordon, M.D., Assistant Pathologist to St. Bartholomew's Hospital.

M. N.—Maurice Nicoll, M.R.C.S., L.R.C.P.

P. H.—Philip Hamill, M.D., M.R.C.P., Lecturer on Pharmacology and Therapeutics, St. Bartholomew's Hospital, and Assistant Physician to the Metropolitan Hospital.

P. H.—The late Pantland Hick, M.D., B.S., Assistant Physician to the Liverpool Royal Infirmary.

P. L. M.—P. Lockhart Mummery, M.B., B.C., F.R.C.S., Surgeon to St. Mark's Hospital, and to the Queen's Hospital for Children.

P. P. L.—P. P. Laidlaw, B.C., Gordon Lecturer in Pathology, Guy's Hospital.

P. W. B.-S.—Fleet Surgeon P. W. Bassett-Smith, C.B., Lecturer of Tropical Medicine, Royal Naval Hospital, Haslar.

R. A. B.—R. A. Bolam, M.D., M.R.C.P., Physician to the Skin Department, Royal Victoria Infirmary, Newcastle; and Professor of Medical Jurisprudence, University of Durham.

R. C. E.—R. C. Elmslie, M.S., F.R.C.S., Orthopædic Surgeon to St. Bartholomew's Hospital; Assistant Surgeon to the Metropolitan Hospital; and Medical Officer of the Cripples' Schools, L.C.C.

R. K.—R. Knox, M.D., Director of the Electrical and Radiotherapeutical Department, Cancer Hospital; Hon. Medical Officer in Charge of the Electrical Department, Great Northern Hospital.

R. L. J. L.—R. Llewellyn J. Llewellyn, M.B., M.R.C.S., Late Resident Medical Officer, Royal Mineral Water Hospital, Bath.

R. R. B.—R. R. Bennett, B.Sc., F.I.C., Member of the Examining Board on the Pharmaceutical Society of Great Britain.

R. W. M.—R. W. Michell, M.D., F.R.C.S.

S. A. K. W.—S. A. Kinnier Wilson, M.D., M.R.C.P., Assistant Physician to the National Hospital, Queen Square.

S. E. D.—S. E. Dore, M.D., M.R.C.P., Assistant Physician for Diseases of the Skin, and Lecturer on Skin Diseases, Westminster Hospital; Physician to the Skin Department, Hampstead General Hospital.

T. C. A.—Sir Thomas Clifford Allbutt, K.C.B., M.D., F.R.S., Regius Professor in the University of Cambridge.

T. G. S.—T. Grainger Stewart, M.D., F.R.C.P., Assistant Physician to the National Hospital, Queen Square, and to the West London Hospital.

T. J. H.—T. J. Horder, M.D., F.R.C.P., Assistant Physician to St. Bartholomew's Hospital; and Physician to the Cancer Hospital.

T. R. E.—T. R. Elliott, M.D., F.R.S., Assistant Physician to the University College Hospital.

V. E. H.—V. E. Henderson, M.D., Professor of Pharmacology, University of Toronto, Canada.

V. G. L. F.—V. G. L. Fielden, M.D., Demonstrator of Materia Medica and Pharmacology, Queen's University, Belfast.

W. C. B.—W. Cecil Bosanquet, M.D., F.R.C.P., Assistant Physician to Charing Cross Hospital, and to the Brompton Hospital for Consumption.

W. C. S.—W. C. Sillar, M.D., B.Sc., Lecturer on Experimental Pharmacology to the University of Edinburgh.

W. E. D.—W. E. Dixon, M.D., F.R.S., Professor of Materia Medica and Pharmacology, King's College, London; and University Lecturer on Pharmacology, University of Cambridge.

W. D. H.—W. D. Harmer, M.C. (Cantab.), F.R.C.S., Surgeon in Charge of the Throat and Nose Department, St. Bartholomew's Hospital.

W. G. B.—W. Girling Ball, F.R.C.S., Assistant Surgeon, St. Bartholomew's Hospital, and to the East London Hospital for Children.

W. H.—Wilfred Harris, M.D., F.R.C.P., Physician to St. Mary's Hospital, and to the Hospital for Epilepsy and Paralysis, Maida Vale.

W. H.—William Hill, M.D., Surgeon for Diseases of the Ear, Nose and Throat, St. Mary's Hospital.

W. J. D.—Walter J. Dilling, M.A., B.Sc., Lecturer on Pharmacology in the University of Glasgow.

W. J. S. B.—W. J. S. Bythell, B.A. (Cantab.), M.D. (Vict.), Hon. Physician to the Ancoats Hospital, Manchester (Electrotherapeutic Department); Medical Officer to the X-Ray Department of the Manchester Children's Hospital.

W. L. B.—W. Langdon Brown, M.D., F.R.C.P., Assistant Physician, St. Bartholomew's Hospital; and Physician to the Metropolitan Hospital.

W. R. B.—W. Rowley Bristow, F.R.C.S., Chief Assistant, Electrical Department, St. Thomas's Hospital.

INTRODUCTION

If for a moment we cast a glance backwards over the fields of the history of Medicine we shall see that Therapeutics has been fed from three main streams; not flowing in several beds, but, for much of their course at any rate, confluent. These three streams may for the present be signified as the Physical, the Empirical, and the Magical. The Physical may perhaps be called also the Rational method. Its doctrines and practice were developed in the great Hippocratic and Alexandrian Schools, and consisted in the study and application to disease of those mechanical and physical conditions on which normal health depends. It was largely, but not wholly, an especial direction and modification of the principles of hygiene, such as the influences of "Airs, Waters, and Places"; of exercises, active and passive, of dietetics, and so forth. In such a therapeutical system, a system of natural forces and conditions, flourished, as we should anticipate, a great, nay for that time a marvellous, school of Surgery.

But at no period was Therapeutics wholly independent of Empiricism. Early in his time Man discovered that certain substances entering into the body were so soon or even so instantly mischievous that the link of cause and effect was manifest even to a humble intelligence. Animals indeed have no little knowledge, by instinct as we say, what to take and what to avoid; a blind but not ineffectual empiricism. Thus Man learnt that not only in hostile but also in quiet things lay hid powers of evil; and if of evil why not likewise of good? Thus for good and evil, as weapons against his enemies, or as succour for himself and his tribe, Man laid the foundations of an empirical Medicine, such as ultimately we find, for the vegetable world, in Dioscorides. And out of empirical Medicine arose botany and zoology. The third or magical method of Therapeutics, very largely though not wholly of Oriental origin, consisted not in the natural (το φυσικὸν) but in supernatural or præternatural methods; in the aid of divine or demonic beings or occult influences. In European (Mediterranean) civilisation magical or mystical Medicine may be traced to the School of Pythagoras and the Sicilians, though their doctrines were soon swollen, and even overwhelmed, by grosser superstitions of Egyptian and Asiatic lore.

And so, with the temper and tides of nations and of cultures, have these three streams contributed, and do still contribute, to the practice of Medicine. If a few centuries ago the medicinal herb was to be culled only under astrological rules, if the healing waters lost their virtue until the angel stepped again into the well, so to-day herb or water is administered with the sauce of "suggestion." We refine our superstitions before we dismiss them. Thus, partly in an undisciplined empiricism, partly under the influence of magic, or magical suggestion, has grown up the monstrous pile of drugs, mineral, animal and vegetable, under which physician and pharmaceutist are groaning even to-day.

Once, for my sins, I was persuaded to join myself to a somewhat large Committee of the College of Physicians for consideration of the Pharmacopœia; or was it a general meeting *ad hoc* of the Fellows? I forget, and it matters not. Some of us were in favour of a drastic purgation, of a still further reduction of the mass, if not to the Wilksian "half dozen," at any rate to some handy and select circumscription. But no: no sooner did one of us conspirators lay hands upon a half-forgotten outlier of the collection than up sprang some colleague, or more than one, to declare that the defalcation of this substance would be to deprive him of one of the most precious of his remedial means. And so we proceeded, or so we stood still. I remember one of us, I trust not I myself, while speaking quite respectfully of "stomachic tonics," yet demurred to the multitude of this category, the number of vegetable bitters of which a smaller number might surely suffice. At length a daring spirit, coming to grips with detail, proposed to eject the individual "Chiretta." Who, he was bold enough to ask, who on earth ever prescribed Chiretta? Or if such an one there be, let his curiosity be satisfied with Gentian or Calumba! But even Chiretta had her champion. Personally, I penitently admit, I had seldom, perhaps never, heard of Chiretta, but therein lay a part of my ignorance and indifference as a practitioner of medicine. So, I believe, in the end we

were content to do, what most Committees do, to express admirable general sentiments, and then refuse to touch any particular proposition of change.

Perhaps, deep down in our thoughts, still flowed something of the stream of magic. Gentian and Calumba grow on Jordan, Chiretta is perhaps of "Mesopotamia." The champion of Chiretta, like the rest of us each with his own Chiretta, went home no doubt to prescribe his specific for an interesting patient, who again at her tea-table passed round the new and mysterious prescription to her gossips, and impressed by its mystery found in it a potency not vouchsafed to a more vernacular root.

As we say of our appetites, that being human they cannot, or ought not to, be extinguished, but are to be sublimated into more spiritual gifts, so is it with magical medicine. The *shaman* in his horns and feathers, or the more dignified *hakim* of Scott's novels, the one with his bloody instruments, the other with his precious balm or magical powder, in a more conscious and analytical age is succeeded by Mrs. Eddy and the ministers of Emmanuel. The *shaman* and the *hakim* were as sincere as was Paré with his puppy fat, and more sincere than Dr. Honeyman of Harley Street; and who is to throw the first stone at any of them? Magic was never a mere imposture, it appealed and appeals to-day to a large function of human nature. As the officers of the Salvation Army tell us, coarse and elementary natures need coarse and elementary stimulants; but the appeal, the appeal to faith and hope, is the same. The call is to the emotions to fill the sails of the medical bark; without a fair wind the prettiest medical craft may make slow way or none. Magical medicine springs therefore from a perennial source, and runs with the other currents; if, at times, like the Aar and the Rhone, the yellow and the sapphire streams run for many a mile without commingling.

Empirical medicine also has served us tolerably well; it is experiment, if not methodical experiment; without it we should have been poor indeed. For instance, our precious possession of the Jesuits' bark, or again, of colchicum, depended upon a therapeutical "shot"—a shot, one of a million, which hit the mark. The medicine was picked up, as gold has been picked up, by the navvy prospector innocent of geology; but the turn of the geologist follows, of him who tells men where the treasure may lie, and who finds it not by haphazard, but by a study of the structure of the earth.

And so we come back to the first stream—the stream of rational medicine, of remedies found by more and more searching analysis; but many a year will come and go before the scientific therapeutist becomes independent of the empiric. While the scientist is bringing thyroid extracts for myxœdema, or salvarsan for syphilis, the empiric brings iodide of potassium for the ray fungus, and the mystic enriches his formularies with Chiretta. Likewise it is said, but with less probability, that we shall always have to recognise "psychotherapy," the personal ascendancy and suggestiveness of the physician, with humbug as its inevitable shadow. Hope and faith, wisdom and purity are but incidentally the concern of the physician. At present we have to do with ill-educated patients: one man in illness is a great baby, another a dictatorial ass; the "suggestibility" of the patient is a legacy of the ignorance and pretension of the therapeutist, and of the unscientific state of the public mind; as therapeutics become more positive and the patient better instructed this wistfulness will vanish. No obsequious "tact," or "suggestion," is required nowadays to carry out an operation for appendicitis, because every silly lady thinks she knows all about it; some day the treatment of a pneumonia or of a gastric ulcer will be as intelligible and imperative, and stand in as little need of "psychological" garnish.

Among the many signs of promise in this bright morning of Medicine is our universal return, lay and medical, to that positive medicine of the great Greek period to which I have alluded. Even for the smart tea table the motley prescription is losing its "suggestiveness;" fine ladies who neglect their own children, are in a fuss about the babies of the poor, and we are all in a dilemma about the feeding of the children whose brains are under "education." The hygiene of life, inculcated by the chastening of the modern doctrines of tuberculosis—a chastening which has reached even the butcher and the milkman, of the care of the teeth, of the qualities of diet, of the training of the body, is the care of that preventive medicine which cannot be separated from therapeutics. The planning of cities and the material enfranchisement of the citizen are occupying the attention and, indeed, the drastic hand, of the statesman.

For the sick likewise physical methods are becoming every day more and more relied on. Baths of many kinds, methods and virtues, in England at first somewhat discredited by quackery and commercialism, are coming gradually, though as yet very imperfectly, under the immediate control of the expert physician. We are learning also the virtues of high altitudes, perhaps as stimulants of the bone marrow, of climates, and other natural conditions, as we are discovering more and more new resources in other physical means: in rest cures, passive and active exercises, respiratory gymnastics, electric and ray therapeutics, radio-activity, diathermy, and so forth. The principles

of diet, after some preliminary phases of eccentricity, are now better understood and applied; and under Pawlow's instruction the potency of flavours in diet—even, at a crisis, of fine wines—is comprehended. In Surgery, as in the early treatment of fractures and sprains, in the methods prescribed by Bier, and so forth, physical principles are coming to their own again, and achieving better and better results.

All this is fundamental; but we do not stop here: with surer and surer steps we are exploring the mazes of scientific therapy, in biophysics and in biochemistry; and if in the tangle of clinical phenomena a few chance gains may still be made by chance guesses, yet almost all progress worth reckoning is made more and more from the vantage ground of verified and measured chemical and physiological reactions. How far we are to make way on the more open plain of biophysics is a most fascinating "question." Difficult as its methods are, and fallacious save in the hands of highly skilled experts, yet, when thus exactly carried out, we obtain by them immortal knowledge. The mere mass mechanics of the living body count for much; and thence we penetrate into the secret ways of osmosis, of surface tensions, of ionisation and viscosity frictions restraining the travels of the ions, of adhesions and adsorption also—as seen, for instance, in Grünbaum and Coplan's remarkable asbestos experiments, of gas tensions, of blood pressures, and so on. We learn that some salts "ionise" in the body and some do not; some salts precipitate proteins, some do not; and we are detecting the part played by chloride of sodium in the body and the curious behaviour, positive and negative, of various quantities of calcium salts with the tissues and fluids.

And thus, before we enter upon Chemistry, we learn the true marvel of the cell wall, that wonderful little engine of concentration and inhibition, that centre of activity individual and social. If, as we shall see, much of its functions is to be interpreted by Chemistry, yet much also—as, for example, in the activity of the muscle cell—depends upon simpler physical laws, such as surface tensions. Many phases of the whole bodily system also, such as heat regulation in fevers, must in large part be explained on physical principles. Of inhibition again, of which as yet we know so little, is it metabolic (Gaskell), or is it physical; or not a uniform process, but a balance, a complex or variable function dependent upon place and time?

Thus by solubilities and insolubilities we pass into the domain of Chemistry; "organic" or "inorganic," I see no categorical distinction. Is it by physical law—osmotic or other tension, or by chemical law—solubility in lipoid and insolubility in water—that certain hypnotics, such as veronal or sulphonal, pass through the cell wall, while other cognate bodies are kept out? Is it by physical or by chemical hindrance that tetanus toxin does not reach the central nervous system by the blood stream, or that salvarsan cannot get at the spirochæta embedded in those parts? And, if we have marvelled at the cell wall, our marvel is increased when we contemplate the whole cell as a living being, a microcosm—a co-ordinated system of ferments, some of more general quality, many curiously specific; a system of co-operating phases, active, inhibitory and autolytic. If the balance be so shaken that autolysis prevails, as it may be studied in excised cells kept under living conditions, these lytic ferments escape and sap contiguous cells; and if in greater quantity spread destruction in the whole body (cachexia). These processes, with their illumination of disease, of splenic cachæmias perchance, we are seeing more and more clearly, and realising their meaning for the therapeutist, for him who searches to know how far the activity, if any, of his drug or other agent is a function of its chemical constitution, and how far its virtues are to be interpreted as a key fitting the biological lock (Fischer)?

Again we have to consider the effect of our agents not only in cells but also on cells, for ferments are not in the cells only; the blood abounds with them, diastatic ferments, protein splitters, and others, and is itself a sphere of chemical affinities and repulsions. Can any research be more "practical" than that of Lewis, Barcroft, Wolf and others on the distinction between cyanotic and acyanotic dyspnœa, and their explanation of this kind by falling alkalinity of the blood? If it be proved that every ferment is specific, whether for substances of external origin or for each and every substrate of the body itself, we shall have before us no doubt a vast and multitudinous scheme, but we shall pass out of the sphere of occult agencies into an open field of strategy.

No less liberating and refreshing is the discovery so lucidly and usefully set forth by Prof. Hopkins in his Presidential Address to the Physiological Section at Birmingham in 1913, that physiological and pharmacological discovery, when in its search for the processes of nutrition it was groping in bewilderment on the giddy levels of protein bodies of high molecular complexity, an attempt, in the words of Dr. Fielding Garrison, as baffling as an attempt to calculate the dynamics of will-o'-the-wisps, it was blindly thrusting itself into needless difficulties, was handicapping itself; and that in this research again we, not only may, but ought to, occupy ourselves with bodies of quite simple structure, such as the amino-acids. We may begin to build up our study of nutrition upon substances so simple as to be artificially synthesised. As

Prof. Hopkins put it, the significance of digestion is the very protection of the body from complexes, complexes foreign to itself. Its own structure it builds up with quite simple bricks. And, if we are to believe half what is told us about "vitamines," we are hindered, not by the complexity of such substances, but by their elusiveness, their infinitesimal and intangible proportions. So from all sides we are cheered on what has been a dreary way; our difficulties are not indeed fewer than we had supposed, but they are far more comprehensible.

We are learning, then, that if we are to make headway in the treatment of disease we shall not hunt in the dark for chance missiles, such as codein or uranium nitrate in diabetes. If by invisible means such a bullet be put into our hands we shall not despise it; strategically however we shall begin from the bottom, where there is more light, surer footing, and a way less intricate than we had supposed. We shall find that if many diseases are caused by alien invasion from without, others are due to individual default. In gout or diabetes a rung or two may have dropped out from the ladder of ascent and descent; or perhaps a rung was wanting from the beginning, but its defect, while the body was young, more easily compensated. Observers (Garrod and others) are now counting the rungs of these ladders and, in diabetes, are comparing glycosuria with glycæmia, are observing carbohydrate conversion in fever, are working upon the behaviour of fats and fat-splitting ferments, and testing these by processes as simple as surface tensions; a plan of work which, however refined and delicate, still lies within our understanding and our means.

And so with gout; does it matter if waste run in anions (meat) or kations (vegetables)? What is the chemistry of nucleoses and nucleosides, what the relation of amino-bases to hypoxanthins, etc.? In gout is uric acid in excess or only retained? What does colloid uric acid mean? If the uric acid is retained is this a renal fault? Is it, for example, an increased density of the glomerular membranes? Again, how far may waste be, or ought it to be, used up again? The purin bases have been brought well within the range of our methods, and we see the part they play in nuclein exchange; but so far we have not learned much more about them. Can we yet say how far and in what way, if in any way, they are injurious? With Fischer's help, we can begin by synthesising these bodies, follow up glycosides from uric acid, and speculate on the relation of purin glycosides to gout; but between these terms there is as yet, I fear, many a *hiatus valde deflendus*. In the reports of societies, we read columns of discussion, but little deposit of knowledge. Still now we see the road, and certain milestones; and pilgrims forging ahead.

A very subtle and pretty way of following up the trail of morbid processes is by the methods of staining, brilliantly developed by Ehrlich and ingeniously carried forwards as intra-vital staining by Goldmann, whose premature death deprived us of the full benefit of his researches. Not only by stains can we follow up, as it were, the scent of Nature's tracks into their secret haunts, but the structural constitution which adapts the stain to the natural process enables it so to enter into the action (Fischer's key and lock again), that by another turn of pharmacodynamic ingenuity a stain may neutralise it. Thus Ehrlich found in methylene blue some remedy for quartan fever, for bovine piroplasmosis in trypan red, and indicated some other remedies not as yet perhaps adequately investigated, while Nuttall found in trypanblue a remedy for piroplasmosis in dogs and other animals; however, these few points are but points in a large field of discovery, and have their application in the specific affinities of certain drugs for certain physiological tissues.

In the sphere of Immunity Behring's first exploits raised enthusiastic hopes of a triumph of therapeutics, hopes so far, unhappily, if not extinct very much sobered. Beyond diphtheria and typhoid fever we have gained little certain ground. The result of Sir A. Wright's campaign against pneumonia have yet to be appraised. At many points anaphylaxis baffles the investigator. Tolerance again may compel us, if we would exterminate a parasite, to try to do so, in Ehrlich's phrase, "at one blow," by a *therapia sterilisans magna*.

From such researches emerged the distinction between antitoxic and antibacterial defences, a cardinal distinction for the therapeutist. And as my purpose in this Chapter is to emphasise the way of discovery by simplification, I would call attention to certain of Sir A. Wright's experiments *in vitro* which, because they are in *vitro*, have in my opinion received less regard than they will prove to deserve. I refer to his experiments with ethylhydrocuprein on the pneumococcus (a method extended later by Ehrlich to streptococci). In like manner the comparison of the influence of various agents upon the conspicuous vivacity of trypanosomes in the field of the microscope should lead to valuable results.

Another direction of pharmacodynamic research may well prove to be along the line of immune body and ferment parallelism, if in this brief review I may be forgiven for a phrase so curt and arid.

None of us can touch on the dynamics of disease without a tribute to the magnificent—I can use no less a word for it—the daring and original theory of Ehrlich on what I will call the mechanism of specific affinities. This theory, if from so humble a service I may speak of myself,

has filled me, from the time I first heard of it, with admiration; I have wondered and wonder still, at a conception so far beyond any flights or any visions of my small imagination. It stands worthy of a place beside the serial and ring theory of chemical combination. So far from being a nebulous, or a fantastic idea, every day is proving its explanatory power; as for example in the derivation of the test of Wassermann. Ehrlich's conception will, I believe, take its place as the organon of pharmaco-dynamics. By its use, or at any rate by its inspiration, the therapeutist, working on the special affinities between drugs and tissues, will learn from Ehrlich how to add to the arsenal of the "charmed bullets which strike only the objects for whose destruction they were forged."

The brilliant discoveries in the field of what I may broadly call Tropical Medicine are not only lifting our eyes out of the vague to definite and comprehensible conceptions, but, moreover, our hands to such achievements as those of Ross in Egypt and of Gorgas in Panama.

Nor are these achievements confined to "bodily" disease: the new disposition to positive conceptions has become strikingly manifest in the sphere, hitherto so remote and metaphysical, of "Mental Disease." The secrets of Tabes and Dementia Paralytica are torn from "the lap of the gods"; it depends only on our determination when these horrible scourges shall be brought to extinction. And we shall not rest here; analogy hints to us that not these only but other such grievous adversities of the best part of man, such, let us guess, as Dementia præcox, may be, in like manner, results of tangible poisons to be detected and checkmated.

Of late years we have heard much, and justly, of great advances in Surgery. But Surgery is, of course, only one of the many methods of treating all or any disease. The division of Medicine into inner and outer, with its corresponding bisection of the physician, is a comparatively modern convention, a convention which arose in the Roman and medieval contempt of clerk for craftsman. Hippocrates, Erasistratus, or Galen would have laughed it to scorn. Surgery is either "medicine without diagnosis" or is virtually correlative with the whole field of practice. As for many outward maladies we may need neither knife nor splint, so of few inward can it be said that Surgery will find no place. A surgeon in large practice, making his daily autopsies, is better informed, let us say, on gallstones, gastric ulcer, peritonitis, obstruction of the bowels and so forth than the ablest of his "medical" colleagues. But even yet, I believe, cases of appendicitis or intussusception are, on a point of politeness, carried first to the "medical" wards. It is pathetic to see year by year the physician retiring from large departments of his own affairs in dumb submission to the dead hand of the medieval University of Paris—itself perhaps the most perverse of all the greater institutions of Europe. Some "specialising" there must be; the physician will concern himself with such practice as he finds himself best fitted by taste and skill; but his sphere once chosen, surely as a man of decision he should be regarded as free to use all and any ideas, all and any means of cure within his reach. The present custom puts both "physician" and "surgeon" in a false position, and limits their outlook on their world. The gynæcologists, partly no doubt to avoid multiplication of advisers in cases of secrecy, but chiefly perhaps because a few of them were men of decision, fought and won the battle of freedom for themselves; it is for their "medical" brethren to follow the example.

My friends, the Editors, invited me to write a Preface to this work. On a mountain in Switzerland, far away from books and papers, I have ventured to make this sketch of the new Therapeutics. The sketch, as a sketch, is faulty enough. When I come to read it over I find no allusion to Colloid Chemistry—but this is now, perhaps, a somewhat hackneyed subject; none to Hormones and the Chromaffin system, especially to adrenalin which does not disdain to put on a crystalline form; and so on for many a gap. At the risk of wearying the reader by my personal impressions, I have rambled at large among the discoveries which most have awakened my own enthusiasm, and banished to their own under-world the blind and formal drug-mongering of the elder tradition, and indeed of my own younger days, in the practice of physic. What a joy it would be to start from the present and, with these new visions, to begin it all over again!

T. C. A.

Part I

METHODS OF TREATMENT

GENERAL METHODS

THE DIETETIC FACTOR IN TREATMENT

In order to apply the dietetic factor in the treatment of disease, it is necessary to understand something of the methods of nutrition in the healthy man.

Quantity of Food required.—It is curious that physiologists have never been able to answer definitely the question, "How much ought we to eat?" More than forty years ago, Voit fell back on the instinctive appetite of the average man as his guide, and fixed the minimum protein requirement at 100–125 gm. a day. Atwater has recently come to much the same conclusion by comparison of the diets selected by a large number of individuals in varying conditions, the main difference being that for very hard work the protein was increased to 175 gm.

The following tables were prepared by Von Ranke, based on Voit's work. Table A is for a man not doing much muscular work; table B shows the modifications necessary for hard muscular work—

	A	B
Protein	100	125
Carbohydrate .	240	500
Fat	100	50

Diet B contains 300 gm. of carbon and 20 of nitrogen.

Translating this into the terms of ordinary foods, Waller has drawn up the following diet—

Foundation:	1 lb. bread.
	½ lb. lean meat.
	¼ lb. fat.
Accessories:	1 lb. potatoes.
	½ lb. milk.
	¼ lb. eggs.
	⅛ lb. cheese.

This contains about 330 gm. of carbon and 21 of nitrogen and is, therefore, somewhat richer than diet B. The average day's work requires 3000 calories of energy. Diet B contains 3027·5 calories and would, therefore, appear to be adequate in this respect also.

These conclusions have been seriously questioned by Chittenden, who, by observations continued for six months on himself, his assistants, a number of students and a squad of soldiers, showed that nitrogenous equilibrium could be maintained on about half this amount of protein with no diminution of physical or mental energy, but rather an increase.

In the following diet given by Chittenden, the total protein amounts to 41 gm.—

Breakfast.—Coffee, cream, milk and sugar.

Lunch.—Omelette, bacon (10 gm.), potato, butter, bread (or biscuit), fruit and sugar.

Dinner.—Beefsteak (34 gm.), or lamb chop (32 gm.), peas, mashed potatoes, bread, butter, salad, coffee and sugar.

Chittenden has certainly proved one point of great interest and importance: that the minimum protein requirements of the body are much less than was supposed, but he goes much further and maintains that the minimum is also the optimum. He really produces no evidence in favour of this view, however. He is, in fact, obsessed with the old idea that the body is unable to make any other use of protein food than to repair tissue waste—an idea which other lines of work have rendered improbable. The physiological minimum is not necessarily the physiological optimum.

Experience shows that where there are races taking a protein-rich diet and a protein-poor diet living side by side, the morbidity and mortality of an epidemic are higher in the latter. Again, the rapid rise of Japan corresponds to the adoption of a more liberal nitrogenous diet. To this Chittenden retorts that prosperity causes an individual or a race to elaborate the menu, and that increased food is not the cause of the improvement.

Protein Metabolism

The end products of metabolism of the different forms of protein, though conforming to a certain general type, differ widely in detail, yet the chemical constitution of the tissues remains the same whatever the form of the food protein. Thus, horse's blood is rich in tryptophan, one of the aromatic bodies, while wheat protein such as glidine is very poor in it; yet, if a horse be bled and then fed on pure glidine until it has regained its former weight, the amount of tryptophan in its blood is as great as ever. The change from food protein to tissue protein is much more profound than was formerly suspected.

When Kühne showed that at least a portion of protein is broken down by pancreatic digestion into leucin and tyrosin, the purpose of this apparent waste puzzled physiologists. For it was then believed that animals require their protein ready-made, and are incapable of the simplest steps towards its synthesis. But the discovery of erepsin in the secretion of the small intestine by Otto Cohnheim in 1903, proved that not only a part but the whole of the protein molecule ingested was thus broken down into amino-acids, and that dogs could live as well on a complete mixture of these end products as on ordinary protein.

The Building-up of Protein. — It has been well said that just as a Gothic cathedral cannot be built out of a classical temple without reducing it to its constituent stones, so the protein tissues cannot be built out of the protein food until it has been split up into its constituent groups. To continue the analogy, at the end of the rebuilding there must be many stones which will not fit, and so cannot be built up into the new structure. This explains the apparent waste of nitrogen on feeding a starving person with protein. A large proportion of the administered nitrogen appears in the urine, although the tissues might be thought to be clamouring for protein. But they can only utilise stones of the right shape, as it were; one cell may require arginin, another leucin, and so on. They cannot make use of an entire molecule of protein. The increased excretion of nitrogen represents the fragments that will not fit into the gaps. We begin to see then why protein is one of those things of which, as Hutchison says, it is necessary to have too much in order to have enough.

The wider the choice of protein fragments which the tissue cells are offered, the easier and more satisfactory the process of reconstruction. In this way we can understand the greater resisting power of the tissues to invasion by disease when protein has not been cut down to its irreducible minimum. The more the food resembles the flesh into which it has to be incorporated, the easier the metabolic task. This truth underlies Hopkins' humourous advocacy of cannibalism.

The end products of protein digestion are absorbed as such and pass by the portal vein to the liver. The liver has to select those groups required by the tissues and allow them to pass on, while the others undergo denitrification there. By oxidation and subsequent dehydration they can be converted into urea. But, since urea contains more nitrogen than carbon, and protein the reverse, there will be a considerable amount of carbon at the disposal of the body as a source of energy when this disintegrative process is complete.

Neither are the basic nitrogenous groups which have been split off entirely wasted. They are probably of service in preventing acidosis. It is much easier to produce acid intoxication in a fasting than in a well-fed animal. In carnivora, with their abundant protein diet, there is a marked power of protective ammonia formation, and the source of this ammonia is the NH_2 groups split off from the protein. The functions of protein food are, therefore, three: (1) to repair tissue waste; (2) to supply energy; and (3) to combat acidosis.

The Origin of Urea.—Folin's researches have shown that by far the greater part of the urea in urine comes from this nitrogenous excess, direct from the food, and has never formed part of the tissues. This has an important practical bearing on the value to be attached to estimations of urea. Many far-reaching conclusions have been drawn from such estimations in, for instance, uræmia or the toxæmias of pregnancy, but very little attention has been paid to the diet in such cases. It is obvious that a chronic nephritic who is taking very little nitrogenous food, or any one who is rejecting food by vomiting, necessarily excretes but little urea. For within very wide limits the amount of urea excreted depends on the amount of nitrogen ingested and on very little else.

The Economy of a Mixed Diet.—It may be urged that as protein contains fatty acid groups and generally carbohydrate groups as well, it is capable of sustaining life by itself. This is, to a certain extent true, but practically a purely protein diet is open to grave objections. The diet tables given above show that the body requires fifteen times as much carbon as nitrogen. In protein the carbon to nitrogen ratio is 3 to 1; so that, to obtain all the carbon required from protein would mean a great waste of nitrogen, since for every part of nitrogen utilised there would be four wasted. This would mean the digestion of an enormous amount of protein. It has been estimated that it would require $4\frac{1}{2}$ lb. of lean meat in the day to satisfy the bodily needs if this alone were taken. Such an amount would be almost impossible to digest and it would throw an entirely unnecessary task on the body in the formation of urea. The normal individual is only able, and that much against his will, to consume about $3\frac{1}{3}$ lb. of meat daily for at most three days. Hence the economy of a mixed diet, whereby the carbon required can be obtained from carbohydrate or fat without unnecessary nitrogen. It may be noted that the appetite instinctively selects a mixture of foodstuffs on the same plate and even in the same mouthful. The addition of potatoes to meat and of butter to bread and

cheese, are familiar examples of this. Another disadvantage of an excessive protein diet is that it entails the consumption of many aromatic and sulphur groups which are particularly prone to putrefactive changes by the action of intestinal bacteria.

Protein or its products are absolutely essential to tissue building. The great advantage of some excess of protein beyond the amount required for this, is that it provides energy of a high grade at short notice. A high proportion of the animal protein ingested can be utilised in this way. Gelatine may be looked upon as an imperfect protein in that it lacks the aromatic groups, and it is therefore incapable of entirely replacing ordinary protein in the diet. It is, however, a protein sparer like carbohydrate or fat, but it is so to a much higher degree because it can also supply some of the nitrogenous groups contained in protein. It might be urged that the absence of aromatic groups render it highly suitable in the treatment of intestinal intoxications. Unfortunately, it has only a limited sphere of usefulness here as a large amount of gelatine becomes intolerable to the taste.

Carbohydrate Metabolism

Carbohydrate forms the largest bulk of the diet, even allowing for the fact that, as usually eaten, a considerable amount is in the form of cellulose, which is not digested except by bacterial action and is, therefore, not utilised by the body. It is digested to a limited extent by the saliva if thoroughly masticated, and salivary digestion can proceed for a considerable time in the stomach until the contents become acid. The gastric juice has no further action on carbohydrates beyond hydrolysing starch to a certain extent as any other acid medium would do. It follows, then, that it is the harder, drier forms of carbohydrates which have the best chance of being digested by the saliva, yet, in the treatment of digestive disorders, nothing is commoner than the administration of large quantities of starch in a soft form. As Sir Clifford Allbutt says, "There is no superstition more tenacious of life than that which prescribes carbohydrates to all dyspeptics as 'so digestible,' and into weak stomachs, ready to dilate, is thrown a mass of such a dish as rice-pudding—a bulky food, imperfectly salivated and peculiarly apt to decompose with the disengagement of volumes of carbonic acid gas."

The Functions of Carbohydrates.—The digestion of carbohydrates is completed by the pancreatic juice and the succus entericus of the small intestine. After absorption, mainly as dextrose, one of four things may happen to it. It may be stored as glycogen; it may be stored as fat; it may be consumed at once for muscular energy, and, lastly, any excess over the amount which can be dealt with in these ways will appear as sugar in the urine.

1. **The Storage of Glycogen.**—This is a temporary but necessary expedient, since it is impossible for a large amount of a crystalloid-like sugar to remain free in the circulation; the liver may be looked upon as a carbohydrate bank whose stores can be drawn upon at short notice.

2. **Storage as Fat.**—Lawes and Gilbert showed by their classical experiments that the popular idea of carbohydrates being fattening foods is correct. By feeding pigs on barley-meal of known composition they were able to prove that too much fat had been laid on to have come from anything but carbohydrate.

3. **Carbohydrate and Muscular Energy.**—The earlier experiments on the relationship of carbohydrates to muscular energy failed to take into consideration the influence of diet on the source of muscular energy. On a mixed diet, increased work is not followed by a proportionally increased nitrogen output, but on a purely protein diet the increase of work and nitrogenous excretion run parallel. In other words, the body uses whatever foodstuff is most available as a source of energy. One simple consideration will prove that there is no essential difference between the metabolic process in rest and activity. The respiratory quotient is raised by increased consumption of carbohydrate and lowered by increased consumption of protein or fat. In exercise it is not altered, showing that although the body consumes more during exercise than in rest, it continues to use the various foodstuffs in the same portions.

Carbohydrate is an important source of energy because it constitutes so large a part of the food—75 per cent. of the total ordinary diet, but it has no specific virtue in this respect. In this matter there has long been a discrepancy between theory and practice. Abundance of protein food has been found by experience to constitute the best diet for training, which was difficult to understand as long as carbohydrate was believed to be the unique source of muscular energy. Now we know that protein can also act in this way while, in addition, it renews the machinery by increasing metabolic change and prevents the accumulation of fat. The machinery also appears to work more economically when protein is the principal fuel; there is less distress, dyspnœa and sweating.

In the article on *Diabetes* the objections to the total withdrawal of carbohydrates from the diet are discussed. Here it is sufficient to point out that of all the foodstuffs carbohydrates are the richest in oxygen and that in

their entire absence it is impossible for the oxidative changes in the body to be complete. Hence the production of abnormal acids instead of CO_2 and consequent acidosis. The consumption of as little as 30 gm. of sugar in the day will, however, prevent the occurrence of this acidosis.

Fat Metabolism

Turning next to the metabolism of fat in the body we may inquire first how far the different foodstuffs are responsible for its deposit.

1. **Fat as a Source of Fat.**—If more than a moderate amount of fat is given it is directly deposited. By various methods it has been shown that the fat of the food can directly influence the composition of the fat of the tissues and of the cream in milk.

2. **Carbohydrates as a Source of Fat.**—The proof of this has already been given. It is possible that carbohydrate is the main source of an animal's own fat, the fat of the food being either directly deposited as such or consumed at once. This would accord with the experience of those who have used Banting's method for reduction of obesity, that it is better to allow the patient a little fat than to allow him carbohydrate. In short, carbohydrate is more fattening than fat, probably because of the ease with which it can be assimilated in large amounts.

3. **Protein as a Source of Fat.**—We should not expect protein to be a fattening food, since it is difficult to satisfy the daily requirements of the body with this alone, and therefore still more difficult to acquire a surplus on it to be deposited as fat. That lower organisms can convert protein into fat is certain, but there is no evidence that mammals can effect this conversion, though proteins contain plenty of amino fatty acids. In phosphorus poisoning there is an accumulation of fat in the liver which was formerly believed to be due to degeneration of protein. But Rosenfeld showed that it was due to transference of fat from other parts of the body, for if abnormal fat had previously been given it was the abnormal fat which was found to have accumulated in the liver. The condition is one of fatty congestion. Certain other poisons such as chloroform and diphtheria toxin have a similar action. The normal reactions of the liver are retarded, probably by inhibition of the oxidases. Leathes has shown that one very important duty of the liver in metabolism is to receive the less active saturated fats from the body and to convert them into unsaturated fats which are more oxidisable, and, therefore, more active. Should the liver be unable to do this the tissues are starved of oxidisable fat, while the inactive fat accumulates in the liver. And the greater the "fat hunger" of the tissues, the more will they tend to precipitate fat on to the liver to be prepared for their use. We can understand, therefore, the extraordinary speed with which the liver becomes engorged with fat in such a condition as post-anæsthetic poisoning. But it is quite different from the protein giving rise to fat. In the so-called "fatty degeneration" of sepsis and profound anæmias there is often less fat than in a normal organ, but the degenerative process has set the fat free from its combinations, so that it is obvious to the naked eye or microscope instead of only being extracted by elaborate chemical processes.

Functions of Fat.—The chief value of fat, apart from its mechanically protective function, is its calorific value, amounting to 9·3 calories for each gm. consumed as against 4·1, the caloric value of each gm. of the other two foodstuffs. It is inferior to carbohydrate as a protein sparer, and the breaking down of the tissue protein is not decreased by giving fats to a starving animal or to any great extent in diabetes. Fats can also act as a source of energy though carbohydrates are usually drawn upon for this purpose first. The other main function of fat is to act as a reserve store which can be drawn upon at need.

For all practical purposes fat is only digested by the pancreas and absorbed with the aid of the bile. When fats break down they normally are completely oxidised into water and CO_2. If incompletely oxidised, however, as they are in such conditions as diabetes, mountain-sickness, bronchopneumonia, etc., they form oxybutyric acid which gives rise to diacetic acid and may ultimately decompose into acetone. (See articles on *Auto-intoxication* and *Diabetes*.)

Disadvantages of Fat.—Fat has distinct drawbacks in that it is expensive, and that it is relatively indigestible probably because it partially inhibits the secretion of gastric juice. It is usually disliked by children, who can obtain most of its advantages from carbohydrates, which they generally prefer. In view of its inhibitory effect on gastric secretion, it may be good moral discipline to force a child to eat fat, but it is bad physiology. In hot climates fat is disadvantageous from the amount of heat to which it gives rise, but in cold climates it would be difficult to take sufficient bulk of carbohydrates to supply the necessary heat. Moreover, in the coldest climates, fat is more easily obtained than carbohydrate. It is generally said that stout people feel the cold less and suffer more in heat. A moderate excess of fat in the tissues has the advantage of forming a reserve in the event of wasting diseases. The disadvantage of an excess is that the carrying about of extra

inert material consumes energy which might be better employed. It therefore follows that the obese are nearly always short of breath.

The rôle of each of the foodstuffs having been explained, it will be clear that the diet which contains all of them is a physiological ideal and that, while it is impossible to do without protein, it is also highly inadvisable to do without carbohydrate altogether. Probably the easiest foodstuff to do without altogether is fat, but the objections to this have been already explained.

Milk is often spoken of as a perfect food, meaning that it contains all the foodstuffs approximately in the right proportion, but it can only be considered a perfect food for the infant. The percentages of the foodstuffs required by a man doing hard muscular work and those contained in the solid part of the milk are shown in the following table—

	"Ideal"	*Human Milk*
Protein	18·5	20
Carbohydrate . .	74	50
Fat	7·5	30

It is also too dilute a food for adults, and this limits its usefulness in the treatment of such diseases as gastric ulcer and nephritis. As to inorganic constituents, it is deficient in iron and too rich in calcium, so that prolonged milk-feeding is apt to produce anæmia and tends to thrombosis.

The marked frequency of thrombosis following enteric fever during the South African war has been said to be due to the extensive use of condensed milk which is richer in calcium and poorer in citrates than ordinary milk. Milk has a feebly stimulating effect on gastric secretion; on entering the stomach it curdles, unless the gastric contents are already distinctly acid, in which case a precipitate of caseinogen occurs. Curdling was formerly considered an advantage in that it would prevent the escape of valuable nourishment from the alimentary tract too rapidly, but, as a matter of fact, the use of sodium citrate, which prevents curdling, has proved a great advantage in rendering milk more assimilable. This suggests that curdling has not any real advantage. Curdling is apparently the first stage in the activity of almost all proteolytic ferments, and is therefore more marked with the weaker ferments in the stomach than with the stronger ferments in the pancreas. If tryptic activity is delayed by the addition of six per cent. sodium chloride, curdling becomes much more marked. The conclusion, therefore, is that the formation of a curd, which has certain obvious drawbacks, has no real physiological advantage, and processes tending to prevent its occurrence may unhesitatingly be employed when digestion of milk is difficult. Ordinarily speaking, the addition of 1 gr. of citrate of soda to each ounce of milk will prevent the formation of a dense curd, and this has the further advantage of throwing some of the excess of calcium out of action.

Vitamines.—Lately it has been shown what an important part both in growth and disease is played by other constituents of ordinary foods besides the three main foodstuffs. These are not the saline ingredients but organic substances present in minute quantities and easily overlooked. Hopkins found that when food completely freed from them was given to young animals they entirely ceased to grow, though the normal amount of food was taken. If the material removed by alcoholic extraction were returned to the food, or if minute quantities of milk or fresh tissue extracts were added, the animals grew normally. This may have an important bearing on the dietetic treatment of malignant disease, as the rapid and disordered growth of a neoplasm demands more of these organic substances than ordinary tissues. (See article on *Non-Operative Treatment of Malignant Disease.*) Funk, who has added so much to our knowledge of this subject, found that chickens fed with red rice failed to grow; but that on the addition of some yeast or powdered sarcoma cells to the rice they grew, though not so much as on ordinary diet. Not only may growth be inhibited by the lack of these organic substances, but actual diseases may be induced, such as scurvy, infantile scurvy and beri-beri. According to some, epidemic dropsy and pellagra have a similar origin. Fresh milk contains both an anti-scorbutic principle and a substance inhibiting beri-beri. It is now well recognised that heating milk in an autoclave and sterilisation methods generally result in the loss of the anti-scorbutic principle. Hence infantile scurvy in children entirely brought up on such foods. Holst and Frölich induced in guinea-pigs a fatal disease resembling scurvy by feeding them on barley, oats or rye, and cured them by adding fresh potatoes, apples, carrots, cabbage or lime juice. These were useless in the dry form, and the expressed juice lost its activity if heated or kept long, except lime juice, which was not inactivated by boiling for an hour; the stability of its anti-scorbutic principle probably explains its great value in the days of long voyages without fresh food. To such substances Funk has given the name of *Vitamines*, and he believes he has isolated them in a crystalline form and found them to be basic in character. Thus to the beri-beri vitamine in the outer layer of rice he assigns the formula $C_{17}H_{20}N_2O_7$. He has also found it in milk, yeast, ox-brain and lime juice.

The experiments of Thompson and Caldwell point to the existence of similar substances in meat-extracts which play a part in accelerating growth. We may in consequence have to revise our estimate of the value of beef-tea. Its nutritive content is practically nil, and till now the most positive evidence of its stimulating action has been its exciting effect on gastric secretion. As Hutchison points out, the value of oatmeal in some cases of diabetes may be due to its containing a vitamine, while the old controversy as to the respective merits of white and whole-meal bread assumes a new aspect. Evidently a diet is not necessarily adequate because it is of sufficient caloric value and adequate protein content. "It is necessary that it should contain these unknown substances as well, which act more like drugs than foods, and which may play a specific part in metabolism. . . . The practical result of the knowledge already acquired should be to confirm our old belief in the value of a mixed diet, drawn from as many sources as possible, and also to discourage cranky and one-sided views and practices."

Salts in Metabolism.—That inorganic salts are also essential ingredients is generally agreed, though it must be admitted that many of the experiments relied upon to prove this are now invalidated, since the methods employed would also have removed vitamines. But that "salt action" enters definitely into the life of the cell is certain. The three essential metals are sodium, potassium and calcium, while magnesium and iron are presumably also necessary. (See article on *Salt Action.*) Excess of sodium chloride may cause œdema even in an apparently healthy person. Excess of calcium has been thought to increase a liability to thrombosis, but the liability must be already present. Deficiency of iron in the food can, apparently, induce anæmia. But the list of such influence of salts on disease is a short one. Although deficiency of phosphorus in the diet has been held responsible for vague ill-health and actual disease, there is no satisfactory proof of this.

Dietetic Restrictions.—It would perhaps be misleading to assert that the dietetic factor in the treatment of disease has been exaggerated, but it has certainly been misunderstood. There has been a tendency to regard the body too much in the light of a test tube into which reagents could be poured and a definite reaction produced. But the problem is much more complicated than that. Simple chemical explanations of disease have invariably broken down with increased knowledge. Thus it is now recognised that the albumen of the food cannot directly influence albuminuria, that retention of ingested purins is not the cause of gout, that the dietetic treatment of glycosuria is not comprised in abstention from starch and sugar, and that oxaluria and phosphaturia can still occur when oxalates and phosphates have been carefully eliminated from the food.

Sir William Roberts declared years ago of some dietetic restrictions: "They are for the most part quite unmeaning; they stand on no ground of science or experience, and are gratuitously punitive to our patients." Except where we must forbid something for a perfectly definite reason, our patients' likes and dislikes must be carefully considered; whereas it is our own likes and dislikes that tend to appear in our dietetic schemes. Yet it is extraordinary how often quite opposite methods of restriction may do good. A patient goes to a physician, whose opinion is that all purins are deadly poisons. He is put on a purin-free diet and improves. Tiring of the restrictions, he seeks other advice, and finds another physician who holds that most ills are due to incomplete combustion of carbonaceous foods. These are now restricted, while he takes meat freely, and again he improves. The explanation is he ordinarily eats and drinks too much. Variety of diet stimulates his appetite, while the monotony entailed by abstention from so many pleasant things results in his eating less altogether. This must be remembered in estimating the reality of the success claimed for many curious diets. Of recent years there has been a tendency to search for a highly concentrated form of nourishment, with the minimum of waste. This is a fallacy; for the due performance of peristalsis and the avoidance of constipation a certain bulk of material is required, which must be sought in non-absorbable articles, such as cellulose. A certain bulk is also necessary to give a sense of repletion. For the successful treatment of obesity, for example, non-absorbable material is requisite to give satisfaction without excessive assimilation.

It follows from all this that the physiologist looks askance at many of the schemes propounded by the dietetic enthusiast, whom he regards, often with justice, as a faddist of a more or less dangerous sort. The faddist pays no attention to idiosyncrasy, "the factor that changes one man's meat into another man's poison. . . . We do not yet know why one person can eat lobster-salad with impunity while the slightest indulgence in that dainty by another causes a generalised rash that has on occasions been mistaken for scarlet fever."

Special Diets

Certain diets will be considered under the diseases for which they have principally been employed. Thus the purin-free diet is discussed under *Gout*, and the soured milk diet under *Intestinal Intoxications*. Diets for

diabetes, nephritis, oxaluria and phosphaturia, will be found under those headings, and so forth. Certain other diets such as the "whey cure," "grape cure," and "fruit cure," are really disguised forms of partial starvation which have been used for dyspeptic, arthritic and albuminuric gross feeders of sedentary habits. They have not found any great favour in Great Britain, and are mostly resorted to by the Teuton. But reference may be made to certain well-known dietetic systems which have attained some degree of popularity in this country.

The *Salisbury treatment* consists of exclusively protein diet, only fresh, minced lean meat and hot water being allowed thrice daily. The minced meat may be made into the form of a cake lightly grilled. It has been used in chronic dyspepsia with atonic dilatation of the stomach, in chronic gout and rheumatism, obesity, and some skin diseases such as psoriasis. It is recommended that the diet should not be continued for longer than six weeks, when a return should be made very gradually to a moderate mixed diet. It must be remembered that this diet is apt to throw a strain on the excretory organs and is, therefore, definitely contra-indicated if there is any degree of renal inefficiency. I have also known the symptoms of renal calculus to date from the adoption of this diet for obesity.

The *lacto-vegetarian diet* is advised in cases of raised blood pressure, in obesity with constipation, in gastric and intestinal disorders associated with intestinal putrefaction or functional nervous diseases, in insomnia and cardiac neuroses. According to Hutchison, this diet has the following advantages: (1) comparative freedom from purins; (2) the lessening of intestinal putrefaction; (3) richness in mineral salts, and (4) a more bulky residue in the large bowel which tends to correct constipation. It consists of a vegetable diet with the addition of milk and things made with milk, such as junket. It is clear that such a diet can be of considerable nutritive value, and can be made both varied and appetising. It is, therefore, less open to objection than many special diets.

The drawback to a purely *vegetarian diet* is that the human alimentary tract is adapted for an omnivorous diet. The comparatively small stomach and the meagre size of the cæcum are anatomical points against the suitability of strict vegetarianism. The claims made by vegetarians as to the immunity they obtain from diseases such as appendicitis and cancer are unsubstantiated. Moreover, it is clear that certain diseases such as beri-beri, pellagra, sporotrichosis and tapeworm are acquired from vegetables. One of the principal fallacies in vegetarianism is the assumption that the chemical composition of the food is the same thing as the amount of nourishment assimilated from it, whereas the percentage absorbed is far higher in the case of an animal diet, a large proportion of the vegetable protein and the cellulose simply passing through the intestine.

A *fruit diet* is only another variety of vegetarianism. Though pleasant for warm climates and though superior in energy value to a purely vegetable diet, it is open to the objection that it contains such a high proportion of carbohydrate and that the palate soon tires of so much sugar. It is, however, a useful variant for one meal in the day, such as lunch. As Leipoldt says, "a bunch of well-selected Malaga raisins and a small tumbler of milk make an ideal luncheon, which possesses all the requirements necessary for repairing the body waste and are an excellent change from a ham sandwich and a glass of beer, which contain approximately the same amount of nutritive material."

Methods of Under-nutrition.—Certain diets, such as Banting's and Tuffnell's, frankly aim at under-nutrition and partial starvation.

The essential feature of *Banting's diet* is abstention from bread, milk, butter, sugar and potatoes. It is as follows—

Breakfast.—Four to five ounces of beef, mutton, kidneys, broiled fish, bacon or any cold meat except pork; a large cup of plain tea, and a little biscuit or one ounce of toast.

Dinner.—Five to six ounces of any lean meat or fish, any vegetable except potatoes, one ounce of dry toast, some fruit out of a pudding, any kind of poultry or game, and two to three glasses of good claret, sherry or madeira.

Tea.—Two to three ounces of fruit, a rusk or two, and a cup of plain tea.

Supper.—Three to four ounces of meat or fish, as at dinner, and a glass or two of claret.

It will be noted that this diet is largely protein in character and is, therefore, subject to the same limitations as the Salisbury treatment. Banting himself lost 35 lb. in thirty-eight days on this diet.

Œrtel's system is somewhat similar except that the consumption of fat is restricted more than that of carbohydrates, and great stress is laid on limitation of fluid. (For other dietetic schemes in obesity, see article on *Obesity*.)

Tuffnell's diet was formerly largely used in the treatment of aneurysm in combination with absolute rest. It consists of 4 oz. of bread and butter, 2 or 3 oz. of meat, 4 oz. of milk and 3 or 4 oz. of claret daily. Later observers usually omitted the alcohol but restricted the fluids to 10 oz. daily. It is doubtful whether such a restricted diet is either wise or efficacious. The late Hilton Fagge preferred in his own case to work quietly

as long as he could, regarding this treatment as worse than the disease. The recognition of the large part played by syphilis in the production of aneurysm has led to the practical abandonment of Tuffnell's diet, most authorities preferring a simple, moderate restriction of fluid combined with anti-syphilitic remedies. Kingston Fowler has pointed out the special dangers of Tuffnell's diet when aortic regurgitation is also present.

Some popularity attaches at the present time to the adoption of a régime of absolute starvation, nothing more than water being taken. From conversation with those who have tried both, I conclude that after the first forty-eight hours complete starvation causes considerably less discomfort than a meagre and inadequate diet. Certainly a brief course of starvation seems definitely to have benefited patients suffering from asthma, gout, and various gastric and intestinal disorders. Guelpa's method of complete starvation for five or six days and even more, combined with free drinking of purgative waters has acquired a considerable popularity in certain quarters in the treatment of intestinal intoxications, "sluggish liver," high blood-pressure, chronic arthritis, myalgia, diabetes and obesity. My own experience of it is limited, but I have met those who have expressed themselves strongly as to its value, and it really does not cause serious inconvenience. Such drastic means can, however, seldom be required and are rarely advisable.

Methods of Over-Nutrition.—Other methods aim at definite over-nutrition. Some time ago forced feeding was adopted almost as a routine in sanatoria for consumptives. It has now, however, been abandoned, for although it was found a comparatively easy matter to make a phthisical patient accumulate a considerable quantity of fat, this did not necessarily mean that the disease was checked, and it was even thought that the carrying about of such a mass of inert material was a positive disadvantage. Moreover, the weight is certain to decline as soon as forced feeding is stopped, and this has an unfavourable influence on the patient's mind. In the *Weir-Mitchell treatment* there is also an attempt at over-nutrition, though isolation, rest and massage are also essential features. Fresh milk is given at first every two hours from two to four pints daily, and may be increased even to ten pints. Later on farinaceous food, such as arrowroot or cornflour, and then lightly boiled eggs, fish, chicken, game, red meat and bread and butter as the digestive capacity improves, until the patient can take three full meals a day combined with the same amount of milk partly with the meals and partly between them. This method has been employed with success in the treatment of neurasthenia.

LENHARTZ DIET IN GASTRIC ULCER

In view of the interest which has recently been taken in the Lenhartz diet in the treatment of gastric ulcer, it is advisable to give the exact method employed. The question is further discussed in the article on *Diseases of the Stomach*. Lenhartz maintained that the principles which should guide us in the treatment of gastric ulcer are (1) administration of sufficient food to maintain the patient's nutrition, but at the same time to prevent distension of the stomach, which would occur if a quantity of milk adequate to maintain nutrition were given; (2) a diet rich in protein, which fixes the hydrochloric acid by combining with it and thus prevents its influence in continuing the ulcerative process. Bolton has shown clearly that hyperacidity is a potent

factor in preventing the healing of gastric ulcer. Lenhartz thought these indications were best fulfilled by giving small quantities of beaten-up egg and milk, both of which are kept iced. In that way a diet rich in albumen is obtained and distension of the stomach avoided. His plan is to feed the patient by teaspoonfuls every hour from 7 a.m. to 10 p.m., allowing rest throughout the night. Table I gives the original Lenhartz dietary, and Table II shows what that dietary means in teaspoonfuls per hour for the first six days. On the first day the patient is to have two eggs and 200 c.c. of milk, and that means he has two teaspoonfuls of beaten-up egg and four teaspoonfuls of milk every hour. Sugar is added to the eggs on the third day. On the sixth day he gives some raw scraped beef. I think the creatin in the beef is an objection, as it tends to stimulate the secretion of acid, and, therefore, in my cases, I have substituted an equivalent amount of cooked minced chicken. By the seventh day he is taking a little rice, and on the eighth day some soaked rusk. On the tenth day he is having raw ham, according to Lenhartz. That probably suits the German patient, but the English patient does not relish it, and I have simply increased the amount of minced chicken. He recommends an ice-bag being applied to the epigastrium, but I have not often used that. He also recommends that the bowels should not be opened at all during the first week, in order to avoid peristalsis and to promote absorption of the outpoured blood by the intestines, and then, if necessary, to use a small glycerine enema or one of plain hot water. I have not allowed my patients to go as long as that without opening the bowels because of the amount of straining which is required when constipation has lasted so long. He claims as advantages for this method of treatment that the recovery is more rapid, and that it does not deplete the patient because the food supply is sufficient throughout. The sour regurgitation subsides, vomiting and bleeding cease more quickly and relapse is less frequent, while pain ceases promptly, and morphia is seldom required. Moreover, it is possible to treat anæmia earlier and there may even be an increase in body weight during the first week.

Rectal Feeding.—It is generally admitted now that nutrient enemata, as ordinarily administered, have no nutritive value. I have compared the metabolism of patients on such enemata with those supplied with simple saline solution per rectum and have found them to be almost identical. It is improbable that more than 1 gm. of nitrogen can be utilised in this way in the day, an amount for which it is not worth while submitting the patient to so much inconvenience. It is clear that as the rectum is the main site for absorption of water, the food must be presented in a fluid form, and that nutrient suppositories are therefore entirely useless. But, further, the rectum secretes no digestive ferments and, therefore, anything presented to it must be completely pre-digested. Dextrose is the form in which carbohydrates are absorbed and, therefore, it is not surprising that this appears to be the one ingredient of a nutrient enema which is of value. It is probable that any benefits which have hitherto been obtained from nutrient enemata as ordinarily administered has simply been due to the water, dextrose and salt contained. Five per cent. of dextrose and 0·9 per cent. NaCl is the most convenient strength. A pint of this can be given three times a day by gravitation. The funnel should only be raised high enough above the patient to allow the fluid to pass in quite slowly and in no case higher than 18 inches. It should take not less than 20 minutes to administer one pint. I have carefully investigated the question of absorption of pre-digested fat by the rectum, but could obtain no evidence of its occurrence. As far as proteins are concerned, it is clear that, as they are completely broken down to simple amino-acids before absorption, this is the only form in which it is any use giving them in an enema. When I had satisfied myself of the uselessness of the ordinary nutrient enema, I tried a mixture of amino-acids in the form of Fairchild's enemose. But this did not yield good results, and the metabolism as judged by the output of nitrogen and diacetic acid in the urine appeared to be the same as in starvation. Rendle Short, however, obtained much better results by use of milk which had been incubated with liquor pancreaticus for twenty-four hours. His figures show a larger absorption of nitrogen than any others I have seen. Since then I have given on several occasions two to three pints of pancreatised milk daily on this plan. The incubation has been very conveniently carried out in Thermos flasks. In one case, where any food by the mouth caused pain, and Lenhartz's diet could not be tolerated at all, this plan was carried out with marked success, and with hardly any inconvenience. I still hold, however, that, in the words of the late Dr. Gee, "a little food in the stomach is worth a great deal in the rectum." Also the success of Lenhartz's diet in cases of recent hæmatemesis is sufficiently marked to make it seldom necessary to resort to rectal feeding.

Subcutaneous Feeding. — In cases where all food is rejected both by the stomach and rectum, efforts have naturally been made to find a satisfactory system of subcutaneous feeding. But it cannot be said that apart from filling up the subcutaneous tissues with normal saline solution that these efforts have met with any

degree of success. As proteins have to be dealt with by the liver on their way up from the intestines, it is impossible to administer them or their disintegration products subcutaneously. Indeed, as they may be toxic before the liver has intervened, it is positively dangerous to make the attempt. Moderate quantities of dextrose or levulose may be absorbed from the subcutaneous tissues, but there is great danger of producing sloughing of the tissues. It is possible to give them intravenously, but it must be remembered that they will be readily excreted by the kidney, so that the practical utility of such a method is limited to the use of levulose in diabetic coma. (See article on *Diabetes*.) It is claimed that 30–60 gm. of sterilised fat can be assimilated from the subcutaneous tissues in a day and in cases of malnutrition the simpler plan of getting fat absorbed by inunction has met with some success in infants. For this purpose, it is usual to employ cod-liver oil with the addition of a little grass oil to cover its objectionable odour.

W. L. B.

THE DIETETIC TREATMENT OF INFANTS

In the treatment of infantile ailments dietetic measures often take precedence of everything else. Many an illness, whether acute or chronic, is dependent on overfeeding, or on food which is unsuitable in quality or quantity or is lacking in some essential ingredient. Gastric and intestinal disorders are very common. Rickets and scurvy depend mainly on diet. And in all lung affections the diet is of special importance, for over-distension of the stomach by food or gas presses the diaphragm upwards and interferes with the action of the heart.

It must be borne in mind that the food supplies of the sick child, though smaller in quantity than those of an active child in good health, are the same in general composition. Any modification required is usually a reduction in the quantity and percentage composition of the food, especially if there is fever or alimentary disturbance. In acute illness the digestive capacity is diminished, and a diet appropriate in health may then set up gastric or intestinal disorder. Sometimes pre-digested foods are necessary. A liberal supply of water must be given in febrile states. It is important to avoid the administration of drugs likely to cause nausea or dyspepsia. Apart from such a cause, anorexia and vomiting are the infant's only means of indicating that he does not want food; while diarrhœa and undigested stools show that he is being overfed. Attend to the child's tastes, if they are reasonable. Maternal nursing must be continued during infantile disorders, unless serious illness is due to the mother's milk. If this is lacking in quantity or quality, measures can be adopted to improve the supply, or a wet-nurse may be utilised. The breast-fed infant gets more albumin than one brought up "on the bottle"; and, in the case of the latter, the albumin in the milk is often rendered insoluble by boiling. Moreover, the cooking of milk deprives it of valuable biological qualities; and during illness it is inadvisable to change a food supply which apparently agrees with the child. The quantity of maternal milk can be increased by the ingestion of an extra amount of fluid, preferably nutritious fluid, and by extra food, maltine and somatose; by drugs, such as iron, arsenic and strychnine; possibly by lactagol, an extract of cotton seed; and by stimulation of the breasts by massage or faradisation. The fat-content is increased by a liberal protein diet and malt extracts; the protein-content being increased at the same time. Increased frequency of nursing also increases the total secretion of milk and the protein percentage. Exercise reduces the protein percentage.

Hence, in the case of a breast-fed infant suffering from digestive disturbance, the maternal milk supply must be regulated. Usually, it is advisable to feed the child less frequently. If, on the other hand, the child is suffering from some other illness, it may be advisable to let the breast be given more frequently, say every two hours, because of the small quantity taken at any one time. But do not allow the child to be weaned merely because it is ill.

Should it be necessary to stop breast-feeding, it is essential to put the child on a simple food which he can digest. If he has never had any food except mother's milk, it is unlikely that he will be able to digest the ordinary diluted cow's milk suitable for a child of his age and weight. No absolute rule can be laid down as to what can be digested. It depends so much on the nature of the illness, the size and weight of the child, and his environment. As a general principle begin with a food much weaker in quality than that normally suitable for a healthy infant of the same age and weight. The quantity for each meal need not be altered. Similar principles can be applied in the case of a bottle-fed child who is ill, though the diet need not be altered if it is digested and appropriate, except perhaps that the quality may need reduction. Let us consider, therefore, the common and simpler foods, suitable during illness, and take the least nutritious ones first.

Whey is only slightly nutritive but is easily digested. It contains about the same amount of sugar and salts as the milk from which it is prepared, is devoid of casein and practically free from fat, and contains about 0·85 per cent. albumin. If the curd is squeezed through

muslin some of the fat globules and casein particles pass into the whey, making it richer and more nutritious, but the casein is finely divided and does not form curds in the stomach. Whey is easily enriched by adding cream. The addition of one drachm of cream, 16 per cent. fat, to two ounces of whey is equivalent to adding 1 per cent. fat, besides slightly increasing the protein content of the mixture. Whey is usually made by coagulating milk with rennet, the curd contracting and squeezing out the whey. A simpler method is to buy *Sweet Whey Powder* and add one teaspoonful to two ounces of water: it makes an efficient substitute. Tartrated whey, citric acid whey and white wine whey are sometimes used. The last of these is valuable when stimulants are needed. It is, in my opinion, better to rely on brandy, for the dose can be more accurately regulated. Whey is not always suitable and may give rise to "whey poisoning," a kind of intestinal toxæmia possibly due to a qualitative and quantitative difference in the salts, or perhaps some gastro-enteritis.

Ass's milk is a valuable temporary food, somewhat costly. It is quite as digestible as human milk. Babies do well on it for a short time, but I have never found it of great value for more than a month or two. It is rarely necessary to have recourse to this milk, as some of the proprietary foods are quite as satisfactory for temporary purposes.

Proprietary Foods.—The simplest of these for use during illness are various kinds of condensed milk, Allenbury No. 1 Food and Horlick's Malted Milk. Condensed milk must be given in weak solution to start with, *e. g.* one teaspoonful to two or three ounces of water. The high percentage of sugar in the sweetened brands, such as "Nestlé's" and "Milkmaid," may cause flatulent distension. If so, and in cases of intestinal inflammation or catarrh, give an unsweetened brand, such as the "Ideal," adding sufficient sugar to make it palatable. Or the Allenbury Food may be tried. Sometimes a malted food is more suitable and Horlick's Malted Milk, a condensed milk with maltose added, proves valuable.

Peptonised milk may be better than any of these foods. Use either Fairchild's or Allenbury peptonising powders and make it freshly twice a day. Peptonise the milk for fifteen minutes and give it diluted with an equal quantity of water. If this agrees the proportion of peptonised milk can be increased. Sugar is added in the proportion, one drachm to two ounces of milk and water. Use milk sugar if there is enteric disturbance. Sometimes maltose is preferable, or a teaspoonful of malted milk can be added to each feed. In order to pass from peptonised milk to a diet of milk, sugar and water, either reduce the duration of peptonisation gradually or give one feed a day of the modified ordinary milk, and if it agrees slowly replace the feeds of peptonised milk by the new mixture. Provided the peptonised milk is brought to boiling-point, to destroy the ferment, it will keep for hours and not turn bitter. If more fat is wanted in the diet either use for peptonisation the top half of milk, which has stood for three hours in the cold or add cream to each feed.

Desiccated milks are useful in hot weather and in diarrhœal affections. Some are preparations of pure casein, *e. g.* Biogene, Casumen, Plasmon, Protene and Tilia. Sanatogen is a mixture of casein and 5 per cent. glycerophosphate of soda. The addition of these foods to ordinary milk or whey mixtures is a simple method of increasing the protein percentage. *Albulactin*, a milk albuminate soluble in water, can be similarly added to milk to increase the percentage of albumin. It helps to prevent the formation of large curds. *Sweet Whey Powder* is somewhat similar, but contains sugar in addition. Desiccated whole milk is sold under the names of Glaxo and Lacvitum: and desiccated skimmed milk, as lacumen. Such foods are of temporary value, but they are deficient in fat and antiscorbutic properties, and are far removed from fresh foods.

Cow's milk is the main food of an infant who is not breast-fed. In the case of illness, and even in health, it must be modified to suit the child. Unless the milk is of known purity, especially in hot weather, it must be brought to a boil before it is given to the child. Pasteurisation and sterilisation are rarely needed, and they reduce the antiscorbutic properties of the milk. Uncooked fresh milk is more valuable than any food prepared from milk, but there are certain risks attached to its use. Some infants do well on *citrated* milk, undiluted milk with one grain of citrate of soda per ounce. Although as a rule undiluted milk is unsuitable in illness, citrated milk is sometimes remarkably beneficial, even in intestinal disorders.

The simplest modification is dilution with water or some weak cereal decoction. Egg albumin, gelatine and dextrinised foods are also used as mechanical attenuants. The cheapest mixture is that of milk, water and cane sugar. Barley water can be used as a diluent after the first month of life, provided a very weak solution is used at first and the strength is only slowly increased. Much of the theoretical objection raised to giving barley water, or starch in any form, at an early age has been controverted by clinical experience and recent physiological investigation. Various carbohydrates can be used, such as milk sugar, cane

sugar, maltose, dextrins, lævulose, dextrose and starch, provided the quantity is not excessive.

Apart from simple peptonisation the milk can be partially predigested by the addition of *Benger's Food*. In this process of preparation the proteins in the milk and the starch in the food are partly digested. Such a food, in small amount, may also be used from the earliest months of life. It is most valuable if the digestion is weak and during illness.

Or the milk may be malted. Mixtures of milk, water, cream and Kepler's malt extract are often most digestible. The milk is boiled and cooled to 98° F. before the malt extract is added. So, too, the addition of a malted food, such as Mellin's or Horlick's, renders the mixture more digestible and more nutritious. These foods must only be used in moderation or the child becomes unduly fat: and they must not be given to replace the necessary proteins and fat of milk.

Lactic Acid Milk is not often needed. The protein is in the form of casein lactate. Buttermilk is given sweetened and sterilised. Lactobacilline milk is prepared by inoculating milk with huge numbers of lactic acid bacilli. These bacilli, and the free acid, help to prevent intestinal dyspepsia and limit intestinal putrefaction. They are occasionally of value in enteritis and colitis. For infants, mix the milk with two parts of barley water and add cane sugar, half an ounce per pint; for older children give equal parts, or two of milk to one of barley water. Obviously the general diet of the infant during illness is one of milk in its most digestible forms, and carbohydrates. Fats must be given in moderation. Cream is often unsuitable, especially if centrifugalised or containing preservatives. If extra fat is needed, it can be given in the form of olive oil, cod-liver oil, butter, margarine or dripping. The addition of a little yolk of egg is of great value in wasting disorders, for the sake of its fat, iron, lecithin and other constituents. In scorbutic conditions, and all infants fed for a prolonged period on a cooked diet, give fruit-juice in the form of sweetened grape-juice or diluted orange-juice. If necessary, a little potato cream can be added to the milk and vegetable soups may be given.

Meat preparations are rarely necessary. Most of them consist chiefly of salt, water and extractives. Meat jellies, though expensive and innutritious, stimulate the appetite and aid digestion. Small quantities of beef-tea, chicken-tea, etc., are similarly useful. They relieve the maternal fears of starvation, and are valuable especially for fat, plethoric babies in whom it is advisable to reduce the calorific value of the diet.

During the *second year of life* dietetic treatment is carried out on similar lines, but more variety is permissible in the way of carbohydrate foods, puddings, vegetable purées, mashed potatoes and gravy, eggs and fish, and even meat if the child is old enough. At this period, just as in younger infants, the essential principle is to give a sufficiently nutritious diet, palatable and digestible, without overfeeding the child. Well-nourished infants can live on a very limited diet during illness, especially febrile disorders, for many days at a time and with great advantage.

General Directions

For Infants.—Feed every two hours during the first month, from 5 a.m. to 11 p.m.; every two and a half hours during the second month, from 7.30 a.m. to 10.30 p.m., giving also one feed during the night, preferably between 4 a.m. and 5 a.m.; every three hours after the second month from 8 a.m. to 11 p.m. and one feed during the night. After the sixth month, sometimes earlier, and perhaps in cases of indigestion, the child may be limited to six feeds at three and a half hourly intervals, or to five feeds at four hourly intervals.

In artificially-fed infants the frequency of feeding should be the same, and the composition of the food as follows—

In the *second month:* milk 1 oz., water $1\frac{1}{2}$–2 oz., lactose 1 dr. In the *third month:* milk and water, equal parts, 3 oz., lactose 1 dr. Each feed may then be increased slowly by $\frac{1}{2}$–1 oz. a month, up to a total of 5–6 oz. at six months of age. After this the meals may be made stronger by giving more milk and less water in each feed. Cream must only be added in moderation during illness. Barley water may be given instead of water after the third month, or even earlier if it is very weak. In the ninth month, sometimes earlier, the child may be trained gradually to digest more carbohydrate food by giving a malted food, such as Mellin's or Horlick's, next a partly malted food such as Savory & Moore's, and then rusks or Robb's biscuits ("tops and bottoms") crumbled up in milk. During illness it is rarely advisable to give other foods in the first year of life, except in so far as the addition of fruit juice or yolk of egg may be advisable. Even in the second half of the first year a similar diet is generally appropriate in illness, but it can be varied by giving Benger's food, potato and gravy, custard or other milk pudding, bread and milk, biscuits, and bread and butter.

Diet at 12–18 *months of Age.*—6–7 a.m.—Whole or diluted milk, hot or cold, 6 oz., with rusk, stale bread or bread and butter.

8.30–9.30 a.m.—*One of these daily:* a small basin of rusk or bread and milk: of fine oatmeal porridge, Quaker oats, Grape nuts, etc., with

cream or milk; thick milk gruel; or thin milk cocoa with bread and butter or bacon fat.

12.30–1.20 p.m.—*First Course :* a teaspoonful to a tablespoonful of mashed potato or stale bread crumbs, with red gravy, meat juice, chicken or mutton broth, or the yolk of a lightly boiled or poached egg.

Second Course : A tablespoonful of custard, tapioca, ground rice, fine sago, cornflour or semolina pudding, junket, cornflour mould or blancmange. A little fruit juice occasionally. Cold water or milk and water to drink.

4.30–5.0 p.m.—Same as first meal; or thin cocoa with bread and butter, treacle or honey, rusks and plain biscuits.

8.0–9.0 p.m.—Milk gruel 6 oz., Benger's or Mellin's Food; rusk, sponge finger or bread soaked in milk.

Diet from 18–30 *months of Age.*—The child should be fed at the same times and on about the same quantities, the amount depending on the appetite and state of health. For breakfast a lightly boiled or poached egg with bread and butter may be given, alone or as a second course, or bread soaked in bacon fat. For dinner, boiled fish, up to one tablespoonful can be given, pounded up at first, at fifteen to twenty-one months of age. After the child has taken fish for two or three weeks he may have pounded-up chicken and then red meat. These foods must be given with mashed-up potato and greens, at first passed through a sieve. Thus, a suitable diet includes for dinner: egg twice, white meat twice, red meat twice, and a thick vegetable soup once a week. Or, when the child is taking an egg occasionally for breakfast, the first course at dinner should consist of fish, white meat and red meat, each twice a week, and on the odd day a thick vegetable soup, brains, calf's head or sweetbread. Water or barley water may be drunk. At this age baked apple can be given, and stewed fruits free from skins, pips and stones, or mashed-up ripe bananas. E. C.

THE NON-OPERATIVE TREATMENT OF MALIGNANT DISEASE[1]

The treatment of cancer may be considered under two headings—

I. Preventive and curative efforts.

II. Palliative efforts.

These are not distinct from each other. Some efforts at cure relieve symptoms and prolong life. On the other hand, some curative efforts produce pain and discomfort. The use of particular remedies that have this effect should always be considered in terms of the chance of cure in the particular patient concerned.

For the reason that it is the duty of the practitioner to consider first whether or no a disease can be cured, and then, if it cannot, to what degree it can be palliated, the treatment of cancer will be here dealt with in this order. Such a plan necessarily involves the mention of forms of radical treatment that are at present under trial, and of others that have little more than historical or theoretical interest. In a practical treatise such as this much space cannot be devoted to either of these modes of treatment. At the end of this article will be found a scheme of practice in which the treatment will be summarised for different types of case, and due regard will there be given to those measures known by experience to be really helpful rather than illusory.

I. Preventive and Curative Efforts

Curative efforts are either (1) Rational or (2) Empirical.

1. Rational Efforts are based upon some central idea. There are four of these central ideas.

(1) *The idea that cancer is due to errors in tissue metabolism capable of correction by a diet specially chosen.*—It has been thought likely that an association exists between uric acid retention and cancer. And as a "purin-free" diet is by some considered to prevent uric acid retention, these authorities have urged the adoption of such a diet in the treatment of cancer. Trial of such a diet has recently been made in a number of selected cases at the Cancer Hospital, with equivocal results. It was difficult to persuade the patients to submit to the diet, especially in face of loss of weight and general tone resulting from the experiment. It is difficult also to feel convinced of the soundness of the argument underlying the treatment, for the close association of gout and cancer is by no means proved. Even if it were true that cancer developed more readily in patients who ingested purins this would seem to be merely a predisposing cause, to remove which would still leave us far from curing the disease.

By some observers cancer has been thought to be due to the "demineralisation" of foods, as by the use of white flour and of peeled potatoes. Such food defects, if real, could easily be remedied by a full allowance of fresh fruit, by using wholemeal bread and by cooking potatoes in their skins. The "demineralisation" theory runs parallel with the notion that cancer is due to the relatively low content of potassium salts

[1] A brief reference will be made in this article to those surgical measures other than radical procedures which may be undertaken for the relief of patients suffering from cancer. A more inclusive title would be "the treatment of non-removable malignant disease," but if "non-operative" be taken to mean "non-removable" the more common title may still be used.

in the body; it is claimed by some that free administration of potassium salts has cured cancer. Two considerations arise—the first, that it is easy to add potassium salts to whatever treatment of a more convincing sort a cancer patient is having; the second, that the condition most often resembling cancer is gumma, and it may be that the cure of gumma by administration of potassium iodide has led to this notion that potassium salts cure cancer.

An idea of a different and more convincing kind, which may be dealt with under this heading, is that put forth by Dr. Monckton Copeman, and worthy of thorough trial. Dr. Copeman suggests that the cancer cell might undergo retrogressive changes if the tissues were denied those active principles in food termed *vitamines* by Funk. These vitamines appear to constitute the nutritive factor in food, without which such "deficiency diseases" as scurvy are produced. Young and embryonic tissues are specially dependent on these substances for their growth. Removal of them from food, by the use of the autoclave, might conceivably lead to recession of the new cancer cells, the healthy tissue remaining relatively unaffected. This hypothesis is now being tested on as large a scale as is practicable.

(2) *The idea that specific immunity to cancer can be established in a manner analogous to infective processes.*—It is hoped that either by the use of an anti-serum or of a vaccine the patient may acquire passive or active immunity to the disease. The procedures follo very closely upon those adopted for known microbic infections. Despite a large number of trials, little or no success has attended either of these methods in human cancer.

(3) *That the cancer cell is more readily destroyed by certain toxic agents than are the cells of the host.*—This is the principle underlying the great majority of the efforts made to cure cancer. We cling to the fact that the cancer cell, in its hasty nutrition and disordered growth, is a less stable thing than the cell which it is replacing. It should therefore be capable of more easy destruction. The natural history of the cancer cell supports this principle, and the inherent tendency of these cells to autolysis within the tumour suggests the advisability of trying by all legitimate means—legitimate, that is, with reference to the tissues of the host—to precipitate this destruction. The various toxic agents that have been used to compass this desire fall into two groups: *microbic toxins and ferments*, and *drugs*, chiefly certain preparations of the heavy metals. If we regard the chief and the ultimate action of radium and of X-rays as of a chemical nature we must include these measures also under this principle, but this view of the action of radiations is by no means proved; moreover, in the present state of our knowledge it is more convenient to consider radiation treatment separately.

(*a*) **Microbic Toxins and Ferments.**—Into this class of remedies come Coley's fluid, *Micrococcus neoformans* and "anti-meristem." The disappearance of sarcomata under the influence of an attack of erysipelas was the pioneer observation which led to treatment by *Coley's fluid*. The writer's experience of Coley's fluid, both of the market virus and of material specially made, has been disappointing. Considering the fact that this material has now been in use for more than twenty years, the infrequency with which the treatment is embarked upon to-day suggests that other observers are equally discouraged by their results. The desirable effects upon the tumour seem to be in direct proportion to the degree of general toxicity produced, and without this general result the local effect does not follow. The pain and discomfort endured by the patient create, in England at all events, an almost overwhelming objection to the treatment. So much so that few patients have the courage, and few practitioners the conviction, necessary to pursue the method very far. The writer recently endeavoured to raise the resistance of patients to the general effects of the fluid by preliminary inoculation with S. pyogenes vaccine, but the results were not encouraging. It is possible that in conjunction with other methods, such as radiations and arsenic intravenously, doses of the fluid of lesser size than those producing such acute suffering may be helpful. It seems clear that it is only in cases of sarcoma that results are to be expected from the use of Coley's fluid.[1]

Micrococcus neoformans has been used as a vaccine and also to prepare a serum (Doyen's serum). Neither application has proved of service in the cure of cancer. As it now seems proved that this micro-organism is really Welch's *Staphylococcus epidermidis albus*, it becomes obvious that its use as a vaccine might well alleviate certain symptoms due to secondary infection of a tumour, or (especially) of a malignant ulcer. And this alleviation, which undoubtedly occurs in some cases, may have led to the assumption that these preparations cured cancer just as the finding of the micro-organism in the growth led to the assumption that it was the cause of cancer. This form of treatment must therefore be relegated to the list of palliative measures merely.

Antimeristem (Schmidt) appears to be a derivative of a mucor, and has been much advertised of late. The evidence of its beneficial action appears to rest as yet almost solely upon the observations of its inventor.

[1] For directions see Summary.

Diastasic ferments have been largely used, and trypsin has had the longest vogue amongst this class of remedies, on the basis of some observations by Shaw-Mackenzie tending to show that the antitryptic power of the serum is high in cancer patients. Shaw-Mackenzie advocated the subcutaneous injection of trypsin together with the administration of pancreatic extract, duodenal extract and bile preparations by the mouth. This treatment seems of late years to have been largely abandoned.

Allied to the enzymes, perhaps, are certain substances formed in exudates and transudates occurring intercurrently in cancer patients. It has been noticed that on rare occasions cancer resorbs coincidently with the resorption of such exudates. This observation led to the treatment of cancer by injection of the exudate in increasing quantity, both in the patient from whom it has been removed and in other patients. With the same idea to guide them some observers have used blood serum, or blister fluid, for a similar purpose. The writer's experience of such methods is quite negative, and no authentic cases of actual recovery seem available for reference.

(*b*) **Drugs.**—The second group of toxic agents used to destroy cancer cells include chiefly the heavy metals and their compounds. The brilliant work of Erhlich and his colleagues in connection with the spirochæte of syphilis has breathed fresh life into the flagging body of chemicotherapy, and has incidentally given a new stimulus to research in cancer treatment. A large amount of material provided by many thousands of mice successfully grafted with cancer has been available for this purpose. The highly selective action of various substances upon particular cells has led to the trial of many products specially synthesised by the chemist for the purpose.

Wassermann and others have worked specially with the metals of the sulphur group, and have definitely proved that it is possible to cause the complete resorption of mouse cancer of a certain size by repeated intravenous injection of such a compound as selenium-eosin. Eosin was chosen as part of the metal compound on account of its intensely penetrating character. The demonstration that the cancer cell can be picked out for saturation and ultimate destruction, to the exclusion of the cells of its host, by such means as these, constitutes one of the most significant and encouraging discoveries of recent months. Whether such compounds have any similar effect in human cancer remains to be seen. The choice of the actual compound used is, from analogy with the arsenical preparations employed in the treatment of syphilis, of great importance, and the most efficient preparation—one giving highly toxic effects upon the cancer cell, and relatively low toxic action upon the healthy tissues—may require much exhaustive experiment for its elaboration. Other observers have recorded good results in mouse cancer from the use of tellurium and from selenium given by the mouth. *Copper in colloid form* is also on trial and in this country Herschell and others have recorded what they regard as promising results (see Summary). The silicates have had very extensive trial, in the form of simple sodium and potassium salts given by the mouth, at the hands of Zeller and others; and even Czerny is undecided as to whether there is not some curative effect observable from long-continued use of these preparations.

(4) *The idea that radio-activity can produce retrogressive changes in the cancer cell.*—Of all the methods of dealing with inoperable cancer the two that have most success to place to their credit are undoubtedly X-rays and radium. For the treatment of cancer which is inaccessible to the surgeon, for local recurrences and metastatic deposits and as preventive measures against recurrence generally, they are the most helpful modes of treatment available. It is probable that the nature of the action of both remedies is the same, but it is as yet unknown of what this action really consists. The simple view that the radiations merely destroy the cancer cell because of its lower resistance to all destructive processes is hardly likely to be correct, for it can be shown that X-rays perseveringly applied to the body generally, omitting the tumour, lead to a marked diminution in its size. Nor is it likely that the equally simple view that the radiations merely stimulate the healthy tissues to throw off the parasitic cell is any nearer the truth. The action is probably much more complex than either of these explanations suggests. It has recently been suggested that radiations act by inducing chemical analysis within the cancer tissue, as by liberating choline from lecithin, the choline acting in toxic fashion upon the cancer cell. This notion has led to the direct employment of choline by injection. Of late the production of "secondary radiations" within the body has been under consideration, as it is reasonably hoped that the selective action of the method may be thereby enhanced. Knox draws attention to the possibility of utilising the iron of the hæmoglobin in this way and finds better results from radiation treatment when the hæmoglobin is high than when it is low. It may be possible, by combining radiation treatment with such a method as the intravenous injection of metallic copper or selenium to obtain a similarly enhanced effect by the production of "secondary radiations." The consideration which perhaps appeals most disappointingly in respect of the radiation treatment of cancer,

and which makes it doubtful if we can expect from it much more than we have already got, is the great range of the therapeutic use of the remedy. The very fact that radiations are of great service in other diseases seems to impose a limit upon any very selective efficacy in dealing with the cancer cell. That radiations can cause a tuberculous gland to resume its natural size, and a lymphadenomatous one also, and can so effectually reduce the size of a leukæmic spleen, seems to argue against that power of specialised effect which we feel essential in a means of cure of so specific a disease as cancer. In this place, however, these considerations can but be mentioned. It is hopeful to note that there are, in the minds of the experts, advances still possible in technique and in choice of methods, so that we have probably not yet touched the limits of the practical application of either X-rays or of radium.

For the actual technique of the employment of these remedies reference must be made to the special article dealing with them. It may here be said that in the choice of the actual method—whether X-rays or radium—several considerations apply, especially the situation and size of the growth, and whether or no it is ulcerated. Briefly, it may be said that radium is of special value in tumours of the mouth, pharynx, œsophagus, rectum, vagina, uterus and bladder. Also for small and ulcerated growths and where it is possible to introduce the radium into the interior of the tumour. Coincidently, it must be remembered that X-rays are easier of application in general and much less expensive. Should radium emanations prove useful when taken into the body as radium-water the difficulty of widespread application will be overcome, as also, probably, will the difficulty of expense.

Certain *principles of treatment* laid down by Finzi, both for X-rays and for radium, may be quoted in this place; they are as follows—

(i) Use maximal doses.
(ii) Repeat as frequently as is safe.
(iii) Use sufficient filtration.
(iv) Treat thoroughly, not only the growth itself, but any region it is likely a metastasis might exist.
(v) Continue the treatment after all traces of disease seem to have disappeared.

2. Empirical Measures.—Of these little need here be said; their very name is legion. One or two call for remark because of their occasional advocacy by reputable authorities. *Alnus Glutinosa* (common alder) was introduced by Dr. Underwood Gray, who claimed to obtain good results by the use of a liquid extract from the leaves, administered by the mouth. Under observation at two institutions for the treatment of cancer, negative results were obtained, but with this, as with all other empirical measures, it must be remembered that the cases submitted for trial are necessarily well advanced. *Violet leaves* appear to have less claim to consideration. Treatment by *internal secretions* of various organs seems rational, as in Fouler-ton's suggestion that thymus extract should be tried because the thymus may contribute to the immunity of young animals to cancer. Extracts from the *thyroid gland* and from the placenta have also been freely used.

In respect of all reputed remedies in the cure of cancer it must always be remembered that to disregard the fundamental criterion is but to confuse the issue and to delay progress—reference is here made, of course, to the proof of the diagnosis. Absence of histological evidence, however brilliant the result of treatment may appear, always calls for the exercise of forbearance and generally for a decision to remain silent.

II. Palliative Measures

The practitioner in charge of a case of inoperable cancer is only helped directly by what is practical. Some theoretical considerations have been unavoidable in the preceding section, because in the present stage of our knowledge it is imperative to weigh the pros and cons of so-called curative measures, and some of these are highly theoretical. When faced with daily treatment, however, it is the essentially practical measures that count, and the bulk of these are unfortunately palliative only. But there are really very few cases in which there is nothing to do except to negotiate euthanasia, though in the great majority of cases this stage of the treatment arrives sooner or later.

As already stated, if either of the efforts at cure be attempted it is desirable to choose those means which carry with them relief of distressing symptoms. I am fully convinced that *the most satisfactory line to adopt in nearly all cases is a combination of several different measures;* not in a state of panic, but with deliberate choice of a programme. Thus, faced with an inoperable sarcoma, it might be good to lead off with an alternating treatment by X-rays and radium, and, as an additional measure, to give two or three doses of salvarsan intravenously at weekly intervals during a period immediately following the radiation treatment. In dealing with one of the most common of all types of case—that of a woman who has had a cancerous breast removed and who has developed local recurrence that is inoperable, X-rays and radium may again be employed; vaccines should be employed if there is any secondary infection, the diet should be regulated on the lines indicated, and general tonics, with full doses of iron, should be employed.

The question is often raised whether any preventive treatment should be employed as a *post-operative* measure, as by radio-activity. Some authorities recommend that the scar region be treated by radiations for some weeks following the operation, and this is probably advisable. To keep the wound deliberately open for a time and to subject it to X-ray or radium applications, though a practice obtaining in certain continental cliniques, has not found favour in this country.

Palliative Surgical Procedures deserve some mention here. They are frequently of considerable service and are probably less frequently undertaken than should be the case. Rowntree has recently drawn attention to the alleviation of suffering and the prolongation of life that would undoubtedly follow such procedures in selected cases. It should be remembered that secondary changes in tumours play a considerable part in the distress of the patient, especially in the case of growths in the mouth, breast and uterus. Sloughing, disintegration of the tumour mass, discharges, septic absorption and hæmorrhage—these are the complications that can sometimes be modified or actually cured by timely and discreet surgical measures. The best method of partial removal of such fungating masses, and of otherwise clearing sloughing areas, is probably by the knife wherever possible. A method of recent introduction, and which seems very successful in certain cases, is by *diathermy*. The method appears of special service in growths situate in the mouth, rectum and vagina. The apparatus employed produces a high-frequency current of great power. One of the two electrodes is wrapped in wet towels and is placed on the patient's chest, the other is provided with a metal end and is plunged into the growth. The intense heat thus produced in the tumour mass rapidly destroys the tissue. Harmer briefly gives the details of treatment as follows: "The growth must be sponged so that it is quite dry; the electrode is plunged into the growth and the current is turned on for three to five seconds. A series of punctures is made so that every part of the growth is attacked. There should be no bleeding even with vascular tumours."

This method by diathermy will probably replace the use of the actual cautery for such purposes whenever the requisite current is available. Where it is not, resource may be had to the older method, assuming the knife is not adequate. In no case is it advisable to trust to chemicals (caustics) for the partial destruction of these fungating or sloughing growths. Indeed, the use of strong chemicals is at all times undesirable in treating cancer.

Into the same category comes a class of case in which the indications for non-radical surgical treatment are clearer and more often undertaken. Reference is made to such procedures as gastrostomy for œsophageal cancer, gastro-enterostomy for irremovable growths of the stomach, colotomy for inoperable malignant obstruction to the large bowel and cystotomy for similar obstruction to the bladder or urethra. With these procedures may be put the operation of lymphangioplasty for limbs embarrassed by lymphatic obstruction.

The Treatment of the General Health.—This is of great importance, inasmuch as upon the maintenance of the general tone in large measure hangs the progress (whether slow or rapid) of the disease. Plenty of fresh air is advisable, and if an actual *open-air* life is possible without adding to the mental distress induced by the knowledge of the nature of the disease (should this be known) so much the better. In the cases in which secondary microbic infections are present, open-air treatment is specially indicated. *The diet, pace* those authorities who consider meat-eating answerable for the disease, should be liberal and varied, and should contain articles rich in potassium salts (raw fruit, potatoes cooked in skins, wholemeal bread and uncooked milk). *Tonics* are indicated, and if the patient is receiving radiations as part of the treatment, certain metallic preparations should be given with the idea of inducing secondary radiations in the body (iron, manganese, arsenic). Potassium salts may well be added.

The Relief of Pain.—A careful consideration must be given to the probable cause or causes of the pain so as to select the most appropriate measures for its relief. The fact must not be lost sight of that *radiations* act ofttimes by relieving pain, even in their application to parts not immediately invaded by the growth.

Failing any or much benefit by this treatment, the possibility of relief by *division of affected nerves* must be considered. Division of the lingual nerve sometimes gives great relief to the pain of cancer of the tongue, and the division of the sensory roots of the spinal nerves supplying affected areas in the limbs and trunk is occasionally rewarded by a good result. This indication presents itself chiefly in those cases in which there are unbearable paroxysms of sciatic pain in connection with pelvic growths pressing on the lumbo-sacral plexus.

Attempts have been made to produce degeneration in sensory nerve trunks by the *injection* of various fluids, especially *alcohol* (80 per cent.). The method is only of limited application. More recently, intraspinal injections of analgesics have been attempted for the relief of pain in the type of case just mentioned, and it is well worthy of trial.

The local Application of Anodynes to painful

parts is not of much service, unless these are ulcerated, in which case very weak solutions of eucaine and adrenalin (1 in 100 and 1 in 1000 respectively) in a mild antiseptic ointment is perhaps the best application.

Some form of **drug medication by mouth** becomes imperative, sooner or later, in many cases of inoperable cancer. Certain of the coal-tar products should be tried first, such as *aspirin* (gr. x–xx), or *phenacetin* (gr. v–x), or *antipyrin* (gr. x–xv). Pyramidon (gr. v–x) is a valuable adjunct of more recent introduction. An "antineuralgic" mixture may be tried, such as—

℞ Tinc. Gelsemii ♏ x–xxx
Caffein Citratis gr. v
Acid Nitrohydrochlor dil. ♏ v
Syr. Aurantii ʒ ss
Ex. aq., sextis horis.

But in the majority of patients the use of some preparation of opium becomes inevitable. *Nepenthe* and *liq. opii sedativus* (āā ♏ x–xxx), are perhaps the most useful for oral administration, a route which should always be chosen before resorting to hypodermic medication. Ultimately this latter usually becomes necessary if pain is a marked feature of the case, and in slowly increasing doses.

The *mental state* is perhaps one of the most difficult of the problems of inoperable cancer to face the practitioner. The attitude of the patients varies so much that it is not easy to offer advice. The personality of the doctor and the philosophy of the patient are the medicines of greatest avail. Two lessons experience soon teaches: that not every patient who "wants to know the truth" is prepared to hear it, sometimes he least who asks most boldly; and that self-deception is not seldom a valuable analgesic well worth preserving.

The Treatment of Ulceration, Discharges and Hæmorrhage.—Reference has already been made to the function of partial surgical procedures and of methods of cauterisation in this connection; also to the use of vaccines. It frequently happens that direct applications are necessary to check or to control *offensive and irritating discharges.* The two most useful preparations are *Sanitas* (1 in 20 to 40) and *peroxide of hydrogen* (10 vols.). Dry dressings are preferable to moist, unless there is considerable tenderness and local pain, when warm fomentations are comforting.

In uterine and vaginal cancer, the introduction of *acetone* every four or five days after an initial curetting has in some hands given good results. Care must, however, be taken to prevent the action of the drug on healthy parts, as this produces pain. For this reason the lithotomy position should be adopted and a large-sized speculum introduced.

In the *mucous discharge* complicating œsophageal cancer, the administration of belladonna in small doses may produce considerable relief.

Hæmorrhage, if of the frank variety and from an ulcerated vessel of some size, must be met by ligature of the vessel in its healthy course. This proceeding sometimes leads to retrogressive changes in the tumour, and may therefore be undertaken as a preventive measure. If the bleeding is of the nature of general oozing, the use of the actual cautery or the curette to the ulcerated surface is indicated.

Summary of Treatment in Inoperable Cancer

I. General Principles.

1. Combined methods of treatment lead to better results than single methods.
2. Combinations should be effected both in regard to the destruction of the cancer cell and in regard to improving the vitality of the tissues.
3. If improvement follow treatment consider if the disease be not now amenable to radical cure by operation.
4. Continue treatment after apparent resorption of the growth in all cases.

II. Scheme of Treatment.

1. *Efforts at cure.* Consider applicability to particular case of—
   (1) Radiations.
   Radium in small growths, ulcers, superficial tumours and cancer of mouth, pharynx, œsophagus, rectum, uterus and bladder.
   X-rays in large growths, deep-seated masses and diffused invasions.
   (2) Coley's fluid in sarcoma.
   (3) Intravenous injection of colloid copper or selenium.

2. *Efforts at palliation.* Consider, in each case, the indications for—
   (1) Partial surgical procedures.
   (*a*) For removal of the tumour—by the knife, by diathermy or by the actual cautery.
   (*b*) For the relief of symptoms—by gastrostomy, gastro-enterostomy, intestinal anastomosis, colotomy, cystotomy, tracheotomy, lymphangioplasty.
   (*c*) For the control of hæmorrhage and discharge—by curetting or by the cautery.
   (2) Supporting the general health—by fresh air, good food, abundance of potassium salts, tonics (especially iron), and, in secondary infections, by vaccines.

(3) Relieving pain—by reducing secondary infections, by local anodynes, by division of affected nerve trunks or by injection of alcohol, by intraspinal anæsthesia and by drugs (aspirin, phenacetin, antipyrin, caffeine, gelsemium, pyramidon, but usually by some form of opium—nepenthe, liq. opii sedativi or injectio morphinæ).
(4) Checking secretion of mucus by use of belladonna.
(5) Controlling discharges—by vaccines and by local antiseptics (especially Sanitas and hydrogen peroxide).
(6) Treatment of mental state.

T. J. H.

X-RAY THERAPY

Generally speaking, X-ray Therapy, since the introduction of accurate technique, has been giving much more satisfactory and more consistent results.

In the scope of this article it is not possible to discuss in detail all the varied conditions in which the X-rays have been employed as a therapeutic agent.

There are very few diseases in the treatment of which the X-rays have not been tried with varying success. The literature of X-ray Therapy has assumed considerable proportions, and while there are still differences of opinion as to the best method to employ in administering this form of treatment, it is possible to extract reliable evidence from many sources with regard to those diseases in which X-rays can be proved to produce definite amelioration or cure.

With the apparatus now at our disposal we can measure the quantity and quality of the rays administered with great accuracy and the same dose can be administered time after time. The main difficulty is the management of the X-ray tube itself, and experience alone teaches the operator to recognise the varying characteristics of the tubes and to select the correct vacuum for the purpose required. It should be laid down as an axiom, therefore, that X-ray treatment should never be undertaken by any other than a medical man with special knowledge of this subject, or an experienced layman acting directly under his directions.

The exact nature of the X-rays is still a matter of conjecture, but their physical and physiological characteristics are well known. It is with the latter entirely that we are concerned in discussing X-ray Therapy.

Their action is certainly very largely local, although lesions outside the sphere of action of the rays in cases where treatment has been administered to one or more areas has been observed to improve. It is suggested that an auto-vaccination occurs and in certain cases this seems to afford the only explanation of the improvement that takes place.

If this is the case the amount of immunity produced is of a weak character, because retrogression is the rule rather than the exception when the treatment is discontinued. The application of the X-rays in small doses gives no sensation to the patient at the time of application, however big the dose, nor is there any visible effect on the skin after the application.

If a full dose is given, after some three to five days an erythema is produced which is evanescent, gives rise to no symptoms, except perhaps a little irritability of the skin, and leaves no traces. If full doses are given repeatedly at intervals bronzing of the skin and desquamation takes place. If more than a full dose is given X-ray burns occur, and according to the dose given different degrees are recognised. These reactions have been divided into three degrees.

The *first degree* consists of reddening and swelling of the skin, with itching which may be almost intolerable, and the symptoms begin ten days to three weeks after the application. The symptoms diminish in from eight to fourteen days and the skin becomes normal except that pigmentation occurs and persists, and later atrophy of the skin with telangiectasis is seen.

The *second degree* begins earlier after the dose, five to eight days, and the formation of blisters followed by crusts takes place. These may take months to heal and atrophic scars appear as soon as the healing is complete.

The *third degree* appears about the third or fourth day—after going through the processes of the second degree perhaps months after the irradiation an ulcer forms in the centre of the region involved. This is accompanied by intense pain, and spontaneous healing seldom if ever takes place.

It is questionable whether it is ever justifiable to proceed even as far as the first degree for therapeutic purposes. The second and third can only be looked upon as fatalities, and are only mentioned to show the extreme danger of want of care in applying this method of treatment.

The *atrophic scars* which occur after a long course of treatment have undoubtedly become in a good many instances the seat of a malignant new growth. It is, therefore, a matter of great moment to the patient that their production should be avoided as far as possible in cases other than those where malignant disease is the disease under treatment.

It is not possible to discuss in detail the different forms of apparatus used to administer

this form of treatment, but it might be well to mention the essentials for a good outfit.

Current—continuous from main or accumulators.
Coil—ten to sixteen inch.
Interrupter—dipper or jet capable of working as low a speed as 180 interruptions per minute.
Valve Tubes and *Spark Gap* } necessary on high voltages to stop inverse current.
Milliamperemeter—which gives the amount of current passing through secondary circuit.
Qualimeter—to give the degree of hardness of the tube.
Tubeholder—with impervious screen and arrangement for inserting aluminium filters and placing pastille to measure dose.
Tubes—with adequate regulating devices to vary the degree of vacuum.

The management of the X-ray tube is a matter of great importance, and on this factor depends very largely the success or failure of the treatment.

Tubes are classed as "soft" or "hard" according to the amount of residual gas in them.

A soft tube offers very little resistance to the passage of the electrical current and gives out rays of low penetration. These rays are particularly irritating to the skin, while on the other hand a hard tube offers great resistance to the current, which is of very high penetration and acts less on the skin. It is obvious, therefore, that the degree of vacuum necessary for any particular case must be carefully chosen and care taken that it is maintained throughout the exposure.

It is found in practice that the "soft rays" are readily absorbed by filters consisting of thin sheets of aluminium felt or leather interposed between the patient and the tube. All tubes have some form of regulating device by means of which the vacuum can be reduced. These are all worked on the principle of letting some gas into the body of the tube, and this is effected either by passing a spark through a secondary chamber containing some material which can store up some reserve gas and release it when heated, or by means of a hollow platinum rod sealed into the tube which will allow osmosis of air into the tube when heated.

It can be seen that though we are able to determine the quantity and quality of the rays at a given moment, the variation which can take place owing to the changes in the vacuum during a given exposure makes it impossible to estimate an exact dose with certainty by the amount of current passing through the tube in a given time.

The method that is generally employed and which is the most reliable is to employ Saboraud's pastilles. These consist of small discs coated with platinocyanide of barium which change colour on exposure to the rays. The pastille is placed halfway between the anode of the tube and the patient, and a standard tint is supplied with which the change in colour of the original disc is compared. When the standard tint is reached the full dose that can be given without the incidence of erythema has been administered. The usual distance employed from the anode of the tube to the skin is fifteen centimetres.

The disc must be looked at from time to time during the exposure. It is found very convenient to have a tachimeter inserted in the circuit. This is a device which records the number of interruptions of the break, and it can be set to cut off the current automatically at any desired number of interruptions.

Where it is noted, for instance, that 10,000 interruptions with the apparatus in use are sufficient to give the full tint, the tachimeter is set for 8000, and when it reaches that number the current cut off, the pastille examined and the tachimeter set for another 1000, and so on till the full dose is reached.

With good tubes it is found that the pastille will reach the standard tint in practically the same time, and it is therefore possible to give a definite proportion of the full dose by reducing the number of interruptions.

Schultz[1] uses 1/3, 2/3, and 3/4, 4/5 and 1/1 doses for skin diseases by estimating the time for full dose and subdividing the time taken accordingly.

He gives the equivalent of one full dose once in three weeks and no further irradiation until three weeks have passed since the completion of the dose.

It is necessary to know the degree of hardness of the tube as accurately as possible.

A rough test is the equivalent sparking distance or alternative path, *i. e.* the distance between the points of the sliding rods of the discharger at which the current prefers to jump the air-gap rather than to pass into the tube. We speak of a tube, for instance, as a five-inch tube when the points of the discharging rods are five inches apart and the current is passing through the tube, and when any approximation of the points causes the current to leap the alternative path—the air-gap. This measurement, however, is not sufficiently accurate, and a better method is to employ some instrument by which we can compare the opacity of two or more bodies of different densities.

[1] *X-Ray Treatment of Skin Diseases*, 1912.

There are several of these and the simplest is Benoist's Radiochronometer. This consists of a disc of aluminium cut away to form twelve sectors arranged in steps of different thicknesses, one to twelve millimetres. The aluminium in the centre is removed and a disc of silver 0·11 millimetre in thickness inserted. This thickness of silver has the peculiar property of being proportionately penetrable by hard or soft rays. The instrument is examined with a fluorescent screen, and according to the hardness of the tube the shadows of the silver and different thicknesses of aluminium correspond. The number of the "step" is then taken to denote the penetration of that tube in the Benoist Scale. There are other instruments by Walter and Wehnelt on the same principle, but the numbers are slightly different.

An improvement on this is Bauer's Qualimeter. This is suspended and attached to the negative pole of the tube and gives continuous direct reading of the penetration quality of the tube during the whole exposure. This is now in general use. The reading is the same as in the Benoist Scale.

The comparison of the different scales in use is given below.

Benoist / Bauer .	1	2	3	4	5	6	7	8	9	10
Wehnelt .	1·5	3	4·5	6	7·5	9	10·5	12	13·5	15
Walter . .	1	1–2	2–3	3–4	4–5	5–6	6–7	7–8		

Speaking generally with regard to X-ray Therapy, the most striking results are obtained in some skin diseases—very small doses being often sufficient to clear up the condition more or less permanently. Where action on the deeper tissues is required there are a good many conditions where marked amelioration takes place, but permanent cure is the exception.

It will be found convenient to discuss the application of the X-rays under two headings—

1. Cases in which the action on the skin alone is required.

2. Cases in which action on deeper tissues is required—Exophthalmic Goitre, Lymphatic and Myelocytic Leukæmia, Lymphadenoma, Fibromyomata, prostatic enlargement and malignant disease.

In considering the treatment of skin diseases, no apology is made for giving in tabular form the technique of Schultz. His technique has been very carefully worked out after a very long experience of X-ray applications.

He divides skin diseases into three groups which from the therapeutic standpoint react similarly.

Group.	Quality of Ray.	Dose.	Interval between Doses.	Cycle.	Resting Period.
I.	7·5 Wehnelt	1/3	7 days	3	21 days
II.	5–7·5 Wehnelt	1/2	14 days	2	21 days
III.	7–7·5 Wehnelt	4/5 1/1	3-4 weeks	1	3–4 weeks

Group I comprises those diseases which are readily improved or cured by small doses.

Under this heading are found many of the varieties of Eczema (nummular, occupation, horny, seborrhœic, perianal and perivulvar), Chronic Suppurative Acrodermatitis, Hebra's Prurigo, Erythema Nodosum, Lichen Ruber Planus, Psoriasis, Chilblains and the eczematous stage of Mycosis Fungoides.

In Group II are found ulcerative, hypertrophic and warty tuberculous conditions of skin and mucous membranes, Bazin's disease or scrofuloderma, fistulous tubercular sinuses and the tumours in mycosis fungoides.

Under the heading of Group III come parasitic diseases of the hair (Sycosis, Favus, Ringworm), Hyperidrosis, some benign tumours of the skin, Keloid, intractable warts and malignant disease of the skin.

In the above lists only those conditions are inserted in which X-ray treatment is employed with a fair chance of success.

Diseases in which this treatment is contraindicated are Acne, Hypertrichosis, Pigmented Nævi, Lupus, Erythematosus, Kerion and Ichthyosis.

Special mention must be made of the treatment of Ringworm. The evolution of this treatment is due to Saboraud, who was responsible for the pioneer work and to whose researches its present success is due.

It has been found that the treatment of isolated patches is not satisfactory, because other patches of diseased hair make their appearance, and it is advisable in nearly all cases to treat the whole hairy scalp.

The rationale of the application is to produce a complete epilation of the whole scalp, and this is effected by giving five exposures of different areas at one sitting. This can be completed with adequate apparatus in one to one and a quarter hours by Adamson's method, which is now usually employed. This dispenses with the old and tiresome practice of screening the rest of the scalp while each patch is treated.

The hair is cut short and five points are marked on the head, one just above and in front of each ear and three in the middle line, one from one to two inches behind the frontal margin of the hair, the second from one to one and a half inches above the flat area of the occiput, and the third just above the lower margin of the hair at the back of the head. The distance

between any of these adjacent points should be five inches. A full Saboraud dose is given with the anode over each of these points and the central regions of each receive a full dose, while the oblique areas receive a correspondingly smaller dose according to the degree of obliquity. This is compensated for by the extra dose received when the neighbouring area is treated, and it has been found that the sum of these doses corresponds to a full dose and complete epilation is the result. The non-hairy parts only require to be shielded from the rays.

The hair begins to fall about the fourteenth day and complete epilation is complete about the twenty-first to the twenty-fifth day. There may be a few roots left, and these must be carefully removed. As a rule the patient is non-infectious in thirty-five days from the application.

In this condition it is absolutely necessary that the correct dose should be applied. A slight overdose to any patch may lead to a permanent complete or partial alopecia of that area, whereas if the dose be just too small only partial epilation takes place, some diseased hair is left and the complete process has to be repeated after a month to six weeks.

Owing to the risks involved, it cannot be too strongly urged that this treatment should only be applied by experts and that no one who has not had the opportunity of studying it carefully at some institution where the proper technique is being successfully used without mishap should attempt to carry it out.

Exophthalmic Goitre.—The results are satisfactory on the whole and the nervous symptoms disappear fairly early, the pulse-rate falls and later the exophthalmos becomes less apparent but does not generally disappear altogether. Treatment should be vigorous up to the production of bronzing of the skin over the thyreoid and continued at progressively longer intervals until the symptoms disappear.

Leukæmia.—X-rays have a marked effect on the blood cells. The leucocytes are reduced and the red cells increased in number. The spleen becomes smaller and the general condition of the patient very much improved. Unfortunately this improvement is not permanent and relapses are certain to occur. Applications should be made over the spleen, the ends of the long bones and the sternum at varying intervals. A blood count should be done fairly frequently and the dosage should be determined by the count and care taken to avoid reduction of the white cells too rapidly.

A full dose can be given to each area and the treatment can be continued until the number of white cells approaches the normal, when rest should be given and the recommencement of the treatment determined on a subsequent definite rise in the number of white cells.

Lymphadenoma.—Very great improvement is apparent after X-ray treatment and life can be prolonged, but in the vast number of cases recrudescence is observed. The glands disappear in a most marvellous way and with great rapidity.

Treatment by full doses filtered through felt or aluminium must be administered and continued until all glands have disappeared and recommenced on noticing any evidence of recrudescence. No other therapeutic agent has given such promising results, and considering the extreme gravity of the prognosis the applications should be persisted in up to the extreme limit of safety as regards the production of an X-ray burn and continued over a period of years.

Fibromyoma of the Uterus.—There is very little literature on the treatment of this condition in England, but a very large number of cases have been treated by various Continental radiologists and their results have been very satisfactory on the whole.

The rationale of the treatment is that an artificial menopause is produced by the action of the X-rays on the ovary, while at the same time there is a certain amount of direct action on the tumour itself.

Bordier [1] in his paper read at the Electro-therapeutic Section of The Royal Society of Medicine gives the indications and contra-indications for employing radiotherapy. He lays down that the patient should not be less than thirty-nine years of age and states that the cases that give the best results are interstitial fibromyomata, where hæmorrhage is the chief feature and where the tumour is not excessive in size.

He gives a series of irradiations consisting of three cycles, one over the central and one over each lateral region, nine in all on nine successive days with an interval of from twenty to twenty-five days between each series, and finds that from three to four series are sufficient to produce the required effect.

Albers-Schönberg [2] in his last paper on this subject states that in properly chosen cases he has obtained 78 per cent. of cures. He uses two tubes working at the same time, one above and the other below the patient, and gives in each series four sittings of eight minutes each, making in all between $60x$ and $100x$ on Kienbock's scale (this corresponds to 30H–50H units). He recommends that the following types of cases should not be treated by X-rays: pedunculated myomata of the neck of the

[1] *Archives of Röntgen Ray*, No. 146, 1912.

[2] *Archives d'Électricité médicale*, April 10 and 25, 1913.

uterus and all cases where there is any possibility of the added presence of malignant disease, and those where acute retention has been caused by pressure on the bladder. He uses filters of aluminium two millimetres in thickness and advocates the use of a compressed diaphragm.

Hænish [1] gives results of treatment of fifty cases of which 50 per cent. were cured.

All radiologists are agreed on the necessity of using high tubes (8–9 Benoist) which must be capable of keeping up their vacuum during the whole exposure.

Hypertrophy of the Prostate.—Good results have been obtained from irradiation with hard rays. The cases which are most suitable are those where the hypertrophy is not excessive or of very long standing. A series of six séances with a tube of 7–8B. applied through the perineum through a felt filter at intervals of three or four days is recommended, and if improvement takes places in the symptoms after this procedure it is advisable to continue the treatment.

The first effect is to lessen the frequency of micturition and improvement in the flow, and subsequently the urine becomes clear owing to the non-retention of residual urine.

X-rays in Malignant Diseases.—With the exception of Rodent Ulcer the results of treatment of malignant disease is in the main disappointing, although very marked improvement in the symptoms and the local conditions are often obtained and maintained for a considerable period. This may be said, however, that there is no other therapeutic agent but irradiation with X-rays or radium that has such inhibitory action on the cancer cell, and that improvements in the method of application may produce more lasting effects. There seems to be no doubt that the X-rays have a definite selective action on embryonic cells. This is shown very clearly by their destructive action on the cells of the ovary and the testis; but there is another view put forward, that the beneficial action is due to a stimulation of the healthy cells to resist the action of the diseased cells. The difficulty that has to be faced at the outset is to overcome the absorption of the therapeutic rays by the superficial tissues of the body and to obtain the required action on the deeper structures without damage to the superficial parts. If the theory that the action is due to some antitoxin produced in the body is correct, it might be feasible to irradiate different parts of the body with large doses and so avoid any damage to the skin, but the general belief still holds that the action is almost entirely local. It is a common experience to find a local recurrence healing under the influence of X-rays while secondary deposits are forming elsewhere and the patient is steadily becoming worse.

[1] *Brit. Med. Journal*, October 1912.

Under no circumstances should X-rays be employed to the exclusion of operation where operation is possible. Pre-operative irradiation is universally admitted to be unjustifiable.

Treatment should be vigorous and prolonged. Small doses of X-rays at long intervals undoubtedly stimulate the growth of the cancer cell and therefore should never be employed. The older method was to give small doses frequently, and good results were obtained only owing to the frequency of application, the action being cumulative. Since the use of filters has become general it is possible to administer very large doses without any fear of severe damage to the skin. The applications should be given over a wide area beyond the primary focus and continued with periods of rest for a prolonged period. In a hopelessly inoperable case it is justifiable to give extremely large doses, and it has been demonstrated that marked amelioration has been produced, although a cure has not been effected.

In rodent ulcer in the early stage the result of X-ray treatment is very satisfactory, but where cartilage or bone is involved it is better to resort to surgical measures at once, because it is very rare to find that complete healing takes place under X-ray treatment and valuable time is lost because the growth may spread into the deeper tissues and make the task of the surgeon more difficult to completely eradicate the growth. In the early stages sound healing of the ulcer may be obtained by the use of radium, carbon dioxide snow, or ionisation with zinc. Experience of over twelve years, however, shows that recurrence even after many years is the rule rather than the exception, and patients should be advised to keep under observation from time to time and to report at once if any sign of recurrence takes place.

Primary Epitheliomata and Epitheliomatous glands are very little affected by the X-rays, and in some cases have been observed to spread very rapidly after irradiation. It is practically useless to employ this form of treatment. Where enlarged glands in the neck appearing after an operation for epithelioma of the tongue have been noticed to subside they were probably only inflammatory.

Sarcomata sometimes respond to X-ray treatment in the most marvellous manner, complete disappearance of very rapidly growing tumours taking place, but recurrences and metastases nearly always occur. Instances of prolonged arrest of the growths have been reported. It is worth while to treat all inoperable cases, however, because apparent cures up to several years have been known to occur.

Carcinomata.—The situation in which this is found most amenable to treatment is carcinoma of the breast.

Here one may have to deal with a primary growth which has become inoperable before it has been brought to the observation of the medical man, or where the patient absolutely refuses operation when feasible.

In all except the rapidly growing type of case great improvement takes place, the growth becoming smaller and apparently remaining localised. Such patients may continue for years in good health and without pain.

The second type of case is that in which an operation has been performed and recurrence has taken place in the skin or glands with or without the formation of nodules or ulcers accompanied by pain.

Here the results of treatment are most satisfactory for more or less prolonged periods. The nodules disappear, the ulcers become clean and granulate and heal, and the pain is alleviated or stopped. By the time, however, that the above signs and symptoms have manifested themselves, it is almost certain that the disease has affected the deeper tissues, and in spite of the local improvement, extension to the mediastinum, lungs and pleura and metastatic deposits in the bones manifest themselves and cause death.

When we consider the fact that the X-rays have the power to cause the complete disappearance of the cancerous nodules in the skin, it seems only reasonable that early prophylactic treatment after operation is a logical course to pursue. These recurrences must be due to the unavoidable release of some cancer cells into the wound at the time of the operation, and the sooner after the operation that the X-rays can be brought into play to influence these stray cells, the better chance there must be of killing them. It is difficult to prove that this prophylactic treatment is effective, because it is not possible to say in any particular case that these cells have escaped, but a routine course is recommended by many surgeons after any operation where the growth though operable was extensive.

The treatment should be thorough, and the whole of the affected side back and front should be subjected to a series of irradiations, and this should be continued at lengthening intervals for at least a year after the operation.

Sir J. J. Thomson discovered that certain metals give off secondary X-radiations when the rays from an X-ray tube were allowed to fall on them. He found that this radiation is specific for each metal in penetrative power and is the same whatever the quality of the incident ray—silver unit rays being identical with the β-radiation of radium. Hernaman Johnson [1] has made use of this fact, and in cases of partial obstruction of the bowel by malignant disease has administered a fairly large dose of precipitated silver in a meal, and when this has arrived at the required spot (determined by the fluorescent screen), he gives an exposure over the affected region with a hard tube with the object of getting the secondary X-radiation to act at the site of disease. This dose is repeated at intervals and good results as far as symptoms are concerned have been obtained.

In a subsequent paper [2] he discusses secondary X-radiation at greater length and describes his X-ray transformer, in which the patient is screened from the radiation of the tube itself and is only affected by the secondary radiation from the plate of metal on to which the rays impinge. Although the results of treatment by these secondary radiations have not been very striking as regards permanent therapeutic results, enough has been done to make it evident that this method is worthy of further study.

A. D. R.

ELECTROTHERAPEUTICS

There is, perhaps, no therapeutic agent that is so potent for suggestion or so dramatic in its manifestations as electricity. It is, therefore, little wonder that it has been, and is, still exploited by charlatans, with the result that an extremely valuable agency fell into disrepute. Fortunately, however, this phase has passed and the public no longer looks askance at a medical man who employs electricity in the healing art.

The application of electricity to medicine is a subject that involves a certain elementary knowledge of the physical laws involved, and many medical men who "dabble" with electricity fail because they do not possess this: they buy a battery of some kind and expect to work wonders by turning on a switch. Failure naturally results, and they lose faith in the method, whereas their lack of success is often simply because they have not applied their resources efficiently. It is a study that will repay medical men in almost every branch of the profession. Success in the treatment of disease by electricity depends on the efficiency of the apparatus and the technique, but the personal equation cannot be overlooked, and no physician is likely to be successful unless he can inspire his patient with confidence both in himself and in the method he employs.

In the space at our disposal we do not propose to enter into the physical details of electricity, which may be obtained from any of

[1] *Archives of Röntgen Ray*, December 1911.

[2] *Trans. Royal Society of Medicine*, Electrotherapeutical Section, 1912.

the large number of elementary textbooks, nor can we deal at length with the various forms of electrical treatment that involve expensive apparatus, such as the high-frequency and static current. Our purpose is rather to give an outline of the various applications of electricity that a general practitioner, with comparatively simple and cheap apparatus, may himself undertake efficiently.

We have already referred to the suggestive factor in the applications of electricity, and doubtless this may be turned to advantage in certain cases. Elaborate and complicated apparatus has certainly an advantage in this respect, but the average medical practitioner cannot afford such luxury. But, apart from this factor, it is surprising what elasticity a simple galvano-faradic board will give to the man of ingenuity and resource. By various home-made devices with metronomes, clock-work, etc., he can produce most of the effects that the more complicated sets of apparatus will give for stimulating muscular contractions or helping the circulation, and practically all the electrodes required for ionisation may be made by himself to suit the particular needs of each case.

The Galvanic Current.—The ordinary continuous current is the most important in electric treatment; for, although its use is mainly for ionisation, it can be transformed and altered in various ways to give quite a variety of effects. It is derived from batteries of dry cells, from accumulators, or from the town's mains, the first of these being the best for ordinary work. In using the mains a resistance-board must be interposed to reduce the voltage to such limits as are applicable in medicine, *i. e.* from 0 up to 50 or 60 volts. Some form of rheostat to increase the current gradually so that the patient does not receive shocks is also necessary, but this presents no great difficulty.

Various modifications of the constant current are in general use. The simplest is the interrupted continuous current, the interruptions being made either by hand or by an instrument designed for the purpose, such as an ordinary metronome that is adapted in such a manner that it forms a contact at each beat by dipping a wire into a cup of mercury. The effect of this is to give a series of shocks of a more or less painful character (diagrammatically represented thus: ⊓ ⊓ ⊓ ⊓). These are useful for producing contractions in wasted muscles. A better form of this current, and one that is not painful, is produced by sliding the rheostat (the resistance which controls the strength of the current), either by hand or mechanically, so that the current is gradually increased and diminished in intensity. The employment of this current will be found very useful in the treatment of paralysis and various other conditions in which stimulation of muscles is required. The *sinusoidal* or alternating current is another modification of the galvanic current, and is produced by means of a motor transformer. It is, perhaps, the most useful variation that we have for purposes of stimulation. It is represented diagrammatically thus: ∿∿∿∿∿∿ The rate at which the alternations of the current occur is regulated by the speed of the motor (anything from 100 to 3000 per minute), and the best results are obtained by the slower rather than by the more rapidly changing currents.

The great feature is that although the potential is always changing there are no shocks because the voltage is always rising and falling *gradually*.

The **Faradic Current** has been replaced to a great extent by the sinusoidal, but for certain purposes it is of value. A special coil is required, and it should be noted that some of those that are sold for medical work are almost useless as they are altogether too small; the currents that are given out from them are not only too feeble to be effective but also very painful to the patient. Even with fairly large coils, however, the faradic current is much more painful in proportion to the quantity of current passing through the patient than any of the other forms.

The **Static** and **High-Frequency Currents** both require costly and elaborate apparatus and are hardly ever applicable to general practice. But it often happens that these forms of treatment are available in institutions where a general practitioner is in charge, and it is with a view to his guidance that we include these brief notes.

The high-frequency current, commonly known as H.F., is one of great potential and is capable of producing big sparks which are quite harmless owing to the small quantity of current that is passing and the extraordinary rapid oscillations that occur (millions per second). It is the most dramatic and sensational form of current we have, and consequently it has been more exploited by charlatans than any other. Naturally medical men look askance at any form of treatment that is so abused, but, in spite of the haphazard and unscientific methods of many of the institutions that flourish on the credulity of a gullible public, the fact remains that many patients receive great benefit there. It is very much to be regretted that this valuable form of treatment should have got into such hands and have attained notoriety, but that is no reason why medical men should despise it, for we know of no other form of treatment that is so

successful in treating cases that are dependent on vascular tension. The manner in which the current acts is not known, but the later types of apparatus are extremely effective, and are capable of raising the body temperature several degrees, and it is believed by some workers that the thermic effect is the key to its action.

The chief methods of use are (1) condensation, (2) sparking, (3) thermic effects (diathermy).

1. *Condensation* is carried out by placing the patient on a couch that is covered with metal from which he is separated by a mattress. He holds a metal handle that is connected with the top of the instrument, and when the apparatus is working sparks can be drawn from him. The patient experiences no definite sensations, but the treatment has a soothing effect and a general feeling of well-being is produced. This treatment is of service in various ill-defined conditions that may be classed under debility, and it has a pronounced action upon the blood pressure.

2. *Sparking* may be applied directly by means of a metal point, but is more usually applied through vacuum electrodes made of glass; the current from the machine flows into the electrode and induces a current on the outer surface which sparks on to the skin when the electrode is brought near. The method of sparking with glass electrodes has been used for various forms of skin diseases, such as chronic eczema and psoriasis, with fairly good results, but the X-rays and other forms of treatment have replaced it in this field, while CO_2 has taken its place in dealing with nævi.

The direct sparking by means of a metal point is called fulguration, and powerful sparking from H.F. machines has been used in the treatment of inoperable cancers with a certain amount of success, especially when combined with operative procedure as extensive as the nature of the disease permitted.

This method has also been applied to port-wine marks; but although there is a certain amount of improvement it is hardly commensurate with the time and patience necessary in carrying out the treatment.

3. *Diathermy.*—By means of certain modifications in the most recent and powerful H.F. machines it is possible to produce very marked thermic effects. The current may be applied to any part of the body and the temperature raised by several degrees, in fact the albumen can easily be coagulated. The treatment has been applied to various joint affections and other conditions, but as yet the experience of this new therapeutic procedure is limited in this country. This current may also be used locally for surgical purposes and it is probable that it will supersede the knife for the removal of vascular tissues, because as the instrument passes through it seals the vessels with blood coagulated by the heat and prevents all bleeding.

The **Static Current** is a form of electricity that is much used in America and requires elaborate and expensive apparatus. It has not found favour in England, partly no doubt on account of the technical difficulty in producing these currents in a damp climate. The feature of this form of electricity is that the pressure (voltage) is exceedingly high, but the quantity of current (amperage) is low. The instruments produce a current absolutely in one direction that may be used for actuating an X-ray tube; in fact, this form of generator was in common use for this purpose in America at one time. The voltage is so high that sparks of six or eight inches may be produced, but the quantity of current is so small (about one milliampere) that no ill-effects are experienced by receiving a shock of such apparent magnitude.

When the machine is charged and the current cannot spark across a gap it diffuses itself in the air in a brush discharge that gives a crackling sound and electrifies all objects in its neighbourhood. By connecting the patient to one pole and placing him on an insulated stool beneath an electrode connected with the other pole, the patient is "electrified," and sparks may be drawn from him by any person standing on the floor. The "condensation couch" used for H.F. applications may also be employed in conjunction with this machine.

This form of treatment is said to have a very soothing effect and has been used in sleeplessness with some success.

The sparks from the static machine have also been used by some workers for direct sparking, but the high-frequency current is better for this purpose.

Methods of Application

The galvanic, faradic, sinusoidal and all similar currents may be applied locally, by means of suitable electrodes, or generally, the patient being placed in a bath of some kind. The full bath has fallen out of use, as it is impossible to estimate what proportion of the current passes through the patient, and it has been replaced by the four-cell bath of Dr. Schnee, which has found universal favour. Separate earthenware vessels are supplied for each of the extremities, and in each of these baths a carbon electrode is placed. The current can be passed in any direction through the patient as desired, and can be exactly measured.

A word of warning must be given. If the town's mains are utilised for supplying current to baths or instruments, the greatest care must be taken that no water-pipes, gas-taps, electric-fittings or other metal-work connected with the earth are within reach. Very severe, even

fatal, shocks may be received by patients touching such objects when they are in the bath or holding one of the instruments.

Electrodes are the applicators through which the current reaches the patient. Various types are in general use, the most usual being made of metal covered with layers of lint or chamois leather. The most important point is that there should be good contact with the skin, but care must be taken that no part of the exposed metal is allowed to touch the patient, otherwise a burn will be produced by the excessive electrolysis that will take place at this point. For electric massage metal rollers, covered with lint, are employed.

In all cases the circuit through the patient must be completed, and for this purpose a large indifferent electrode is placed on some convenient part of the body. It is most important that this indifferent electrode should be of sufficient size when big currents are used or a burn will result. A feeling of burning will precede the formation of a burn, and this must be borne in mind when patients speak of any pain during an application. In our own work we use pieces of copper gauze of suitable sizes and cover them with two or three layers of gamgee tissue. Instead of employing an electrode, however, when large currents are to be used, it is better to place one of the limbs in a vessel containing a weak saline solution and to make this the return circuit.

Ionic Medication.—When two wires from a galvanic battery, or from any other source of constant (unidirectional) current, are placed in water, electrolysis takes place and the water is separated into its elementary constituents; the hydrogen is given off from the wire connected with the negative pole, the oxygen from that connected with the positive pole. If common salt or any other soluble salt is dissolved in the water, it also is split up into its component molecules, the basic radicle (the sodium) is given off at the positive pole while the acid radicle (the chlorine) is liberated from the negative terminal. If the copper wires are placed one above and one below a pile of damped sheets of blotting paper and the current is allowed to flow through them, it is found that copper can be detected in the blotting paper near the positive pole and penetrating many layers of it towards the negative pole, but that no copper has passed into the blotting paper near the other wire. In the same way the copper could be made to penetrate into the body from a copper electrode placed in contact with the skin. For practical purposes, however, it is not usual to employ the metal directly in contact with the surface, but to interpose some layers of lint soaked in a 2 to 4 per cent. solution of one of the salts of the metal we wish to use, and to place behind it an electrode made of the same metal connected with the positive pole. In exactly the same manner we can drive in acid radicles such as salicylate of soda by connecting with the negative pole a pad soaked in a solution of this salt. The circuit is completed by means of a *large* indifferent pad electrode placed in some convenient situation or by immersing a limb in a bath containing an ordinary carbon electrode.

This method is not limited to the treatment of small areas. A knee can be enveloped in a large pad from which the ions may be driven into the joint or the drug may be forced through a larger area by immersing the legs or arms in baths in which the drugs are dissolved.

The following table shows the most commonly used drugs and the electrode which must be employed—

+ *Driven in from the Positive Pole.*	− *Driven in from the Negative Pole.*
Sodium	Chloride
Potassium	Iodide
Lithium	Sulphate
Sodium	Salicylate
Zinc	Sulphate
Magnesium	Sulphate
Cocaine	Hydrochloride
Copper	Sulphate
i. e. The ions of all metals, etc., and basic radicles, such as NH_4.	*i. e.* All acid radicles.

For ordinary ionic medication a battery that is capable of giving 40 volts is amply sufficient. The quantity of current used varies with the size of the area under treatment and the individual susceptibility of the patient. For small areas it is found that patients will not tolerate more than a few milli-amperes. The minimum current that will be of value is about 3 ma. per sq. cm. for 12 in.; in the treatment of large surfaces, such as a knee-joint, 40 or 50 ma. are easily tolerated by the majority of patients, and in exceptional cases as much as 120 ma. may be given.

Twenty minutes is an average dose, but naturally the length of time needed for each application varies. In ionic medication the greater the current borne by the patient, the deeper will the ions penetrate, hence in some cases it is better to give one big dose, with an anæsthetic, than multiple doses of comparatively small intensity at frequent intervals. Under the influence of an anæsthetic, ionisation can be used to great advantage, for there is practically no limit to the quantity of current that may be passed, provided that no shocks are given. In the treatment of rodent ulcers and small new growths where excision is not indicated this is of great importance, for the

whole treatment may be effectively accomplished at one sitting. A bare zinc electrode is held in firm contact against the surface until the grey appearance extends to one-eighth of an inch, and if the edges are at all heaped up zinc needles are thrust into them until the whole of the affected area has been treated. Healing takes place fairly rapidly and there is seldom any pain. Collodion dressing is all that is necessary and there seems to be very little tendency for these cases to become septic.

The question may be asked, why, if an anæsthetic is necessary, should the ulcer not be excised? The cosmetic effect of ionisation in this way is much superior. There is practically no scarring and there is no tendency to contraction, so that in all operations on the face this should be the method of choice. Moreover, in reasonably early cases a certain cure may be relied upon in practically every instance. Recurrences are seen in all forms of treatment of rodent ulcer, including excision, and so far as our information goes the chances of recurrence with thorough ionisation are rather less than with other forms of treatment.

Electricity in one or other of the above forms has been applied beneficially to a great number of diseases differing widely in their character. The list fortunately includes some affections which are very obstinate in their reaction to other methods of treatment. It is necessary, however, to protest against the indiscriminate use of electricity, especially in the hands of unqualified persons, when experience has shown that there is little or no prospect of any benefit resulting from its use.

In addition to the effects produced by electrical applications upon the local conditions for which the treatment is adopted, their general tonic action must be emphasised, as this is undoubtedly of great therapeutic value in all cases. The appetite and general condition are improved, the patient sleeps better, and in many cases constipation is relieved. The circulation is stimulated, and we are of opinion that when the two- or four-cell bath is used for rheumatoid arthritis, or other lesions, much of the improvement that results is due to the improved circulation through the affected part.

We have included in the following list those diseases in which in our experience electrical treatment has given encouraging results, or in which the published records appear to merit notice.

Anæmia (Chlorosis).—Some form of general electrisation may be usefully combined with other medical treatment, and considerable benefit may often be obtained from the general tonic action referred to above, especially when the sinusoidal current is applied by means of the four-celled bath. Those who have employed H.F. speak well of the results they obtain by the use of the condensation couch.

Anæsthesia (Local).—Local anæsthesia may be induced by the ionisation of cocaine from the positive pole, a 2 per cent. solution being used. The method may be very conveniently employed as a preliminary to the removal of hairs by means of electrolysis.

Arterio-sclerosis.—In this as in other conditions associated with high blood pressure the H.F. condensation couch gives very good results; even a single sitting often produces a marked fall in the pressure. The elimination of waste products by the urine is also increased and the treatment, therefore, may be beneficial in granular kidney.

Carbuncle.—Zinc ionisation, by means of a zinc needle passed into the centre of the carbuncle, not only relieves pain but frequently effects a rapid cure. In bad cases more than one application may be necessary.

Carcinoma.—Zinc ionisation has also been tried in carcinoma; zinc needles are run into the growth and a large current is used. The sloughing of the growth which results is followed by a comparatively healthy ulcer, and healing may then be encouraged by further ionisation through lint pads soaked in a 4 per cent. solution of zinc sulphate (positive pole). Fulguraction by means of H.F. sparking has also been recommended. [For *Diathermy* see separate article.]

Cardio-vascular Affections.—The action of the H.F. condensation treatment in reducing high blood pressure has already been noted. A peculiarity about this method of treatment is that it is equally valuable in producing the opposite effect when the tension is too low, the tendency in both cases, therefore, being to restore the pressure to the normal. (The Bergonié treatment described under *Obesity* is also an important agent in certain forms of heart disease.)

Chilblains.—The constant and sinusoidal currents used with the four-cell bath for half an hour twice or thrice a week brings about considerable improvement, and in some cases actually cures the patient. Half a dozen to a dozen baths usually effect a marked improvement in the chilblains, and in many cases we have found the cure a permanent one. The general health is also much improved, and the patients invariably find that they suffer less from cold extremities in severe weather, even after having only three or four baths.

Constipation and Atony of the Digestive Tract. Nearly all patients when treated with the sinusoidal current for a variety of conditions volunteer the statement that they note a

distinct improvement in the action of the bowels when there is any tendency to constipation. It is most marked when a current of slow periodicity is employed, but it is uncertain whether this is due to the general tonic action and the strengthening of the abdominal muscles or to the direct stimulation of the peristaltic movements of the intestines. Constipation is, roughly speaking, of two types, *i. e.* due to atony of some part or parts of the colon, or to inefficient defæcation. In the former type the best plan is to apply the current by means of pads over the course of the colon or to place a large pad on the back and apply the sinusoidal current by means of a roller electrode to the abdomen, the result being a combination of electrical treatment and massage that is very effective. When, however, the trouble is inefficient defæcation, it is best to apply one pole actually in the rectum with a special rectal electrode, the other electrode being placed on the abdominal wall. The three-phase current is also useful for this class of treatment.

Debility. — The general tonic effect of the four-cell bath, to which attention has already been drawn, is a most valuable therapeutic agent in the treatment of debility arising from overwork, or as the result of influenza, etc. The four-cell bath, using both the constant and sinusoidal currents, is our routine practice for these cases, and, although it is perhaps rather slow and tedious, the results are quite worth the time expended and it is very seldom that the patients relapse. Other workers speak of the results of auto-condensation with the H.F. current with enthusiasm, but our preference is for the four-cell bath.

Diabetes. — In simple glycosuria the H.F. condensation is said rapidly to bring about a complete disappearance of the sugar from the urine. In true diabetes mellitus the treatment does not seem to be of any use.

Dupuytren's Contraction.—See *Keloid.*

Exophthalmic Goitre. — The faradic current has been used largely in the treatment of this disease, and also the ionisation of the gland with potassium iodide (negative pole). But it seems likely that all other forms of treatment will give place to X-ray therapy, as this is in our experience the only reliable means of obtaining improvement.

Fistulæ.—Good results may be obtained from the ionisation of fistulæ and sinuses of all kinds with zinc, provided that they are not due to the presence of a sequestrum or other operable cause.

Gout.—Gouty arthritis may be treated as other forms of chronic arthritis by means of the two- or four-celled bath, and we believe that the effect of the electricity alone is as successful as when salts are introduced by cataphoresis. In acute cases the anode should be applied to the painful joint or joints, and when the subacute stage is reached a mild sinusoidal current may also be used. If preferred, lithium sulphate or carbonate may be placed in the tub or tubs connected with the positive pole.

In the absence of acute joint lesions, gouty patients may be treated upon the H.F. condensation couch in order to increase the metabolic changes; that this actually takes place is demonstrated by the increased output of urea.

Gynæcological Conditions. — *Amenorrhœa.* — When amenorrhœa is caused by anæmia or debility good results may sometimes be obtained from one of the methods of general electrisation. We prefer the galvanic and sinusoidal currents applied through the four-cell bath, or the H.F. condensation couch may be employed.

Vaginitis.—A specially constructed electrode is employed which allows the vagina to be distended with a 2 per cent. solution of zinc sulphate (positive pole). The treatment is usually very successful.

Chronic Endometritis.—The uterus may be ionised for this complaint by means of a specially constructed copper or zinc electrode, connected with the positive pole; the electrode is insulated to within two inches of the end, and is passed into the cavity of the uterus. A current of from 10 to 12 ma. should be used for about 15 minutes. When using a copper electrode care must be taken at the close of the treatment to pass the current in the reverse direction for two or three minutes before attempting to remove the instrument, since it tends to adhere firmly to the cervical canal as the result of the electrolysis. For this reason a zinc electrode is preferable and the results are quite as good with this metal as with copper.

The effect of this method of treatment is usually as successful as that of curetting. A course of from six to twelve treatments is necessary.

Dsymenorrhœa and Menorrhagia may be treated in the same manner; in the latter complaint the hæmorrhage usually ceases after two or three ionisations.

Hæmorrhoids.—In slight cases of hæmorrhoids we have had good results from the use of the vacuum electrode connected with the H.F. machine, but in severe or longstanding cases the treatment is quite useless. We have also had success by means of ionisation with zinc needles.

Headache. — When caused by overwork or general debility, headaches may often be greatly relieved by the faradic current applied to the back and front of the head through large pads. A large faradic coil must be used, as the currents from the small instruments are too painful.

Incontinence of Urine.—Incontinence in children may be treated by means of a pad placed over the perineum, the other electrode being applied to the lumbar vertebræ. In adult females the sphincter may be directly stimulated by a bougie electrode introduced into the urethra. The bladder being full an attempt is made to produce a desire to micturate, and in some cases one form of current appears to be more efficacious than another. We frequently use a combination of the faradic, interrupted continuous and sinusoidal currents, and in many cases we have been very successful. The best results are obtainable in the cases which are a persistence of the nocturnal incontinence of infancy, while some others appear to be unaffected by the treatment. If there is mental deficiency, there is little hope of benefit.

Insomnia. — Electricity certainly cannot be claimed as a specific for insomnia, but in some cases relief may be obtained from the use of the faradic current, applied to the head as in the treatment of headache. Static electricity and the H.F. couch have also been recommended, but we have not found the results very encouraging.

Keloids and Dupuytren's Contractions. — The ionisation of these conditions by chlorine ions (sodium chloride, negative pole), usually gives good results; large currents, up to 60 or 80 ma., must be used, and the treatment must be carried out thoroughly. We ourselves prefer to treat keloids with the X-rays.

Locomotor Ataxy.—Faradism of the spine has been much used in the treatment of locomotor ataxy, and certainly appears to relieve some of the symptoms. We have not, however, observed much improvement from the use of this or any other form of electrical treatment.

Lupus Vulgaris. — Ionisation must now be considered as one of the alternatives to the Finsen and X-ray methods of treatment for lupus, and it offers a very good hope of success. When the surface is ulcerated, direct ionisation with a 4 per cent. solution of zinc sulphate on a pad (positive pole) may be carried out; if, however, the surface is not broken it should be first painted with sodium hydrate, and the thick cuticle scraped off before the treatment is commenced. In some cases the apple-jelly nodules prove very resistant, and they may then be removed by the zinc needle inserted into the centre of each nodule.

The cosmetic result of ionisation in lupus is very satisfactory; it compares favourably with that of the Finsen light, and is far superior to the average X-ray result, as there is no danger of the formation of telangiectases.

Mucous Colitis and Ulcerative Colitis. — There are few diseases in which the medical treatment is less satisfactory yet with ionisation this class of case yields very satisfactory results in the majority of instances, although a certain number fail to react to treatment of any kind. Of course before resorting to ionisation or any other form of treatment, all possible sources of septic absorption must be carefully sought out and a rigid treatment of all suspicious teeth insisted on, not forgetting that bridges that look excellent may harbour decaying food debris that cannot be cleared out.

The treatment consists of ionisation with zinc or copper into the large intestine from a solution of one of the salts. The current chooses the paths of least resistance and carries with it the ions that we wish to introduce. We employ zinc sulphate solution (4 per cent. positive pole), and inject one and a half pints, a quantity that is ample for irrigation of the whole of the large bowel. Smaller quantities should be used at first until it is found that the patient will tolerate this quantity. A special rectal electrode should be made—a piece of zinc rod with a hole through is what we employ, and in order to avoid the electrolysis that would occur at the sphincter, we insert it in a rubber finger-stall with a few holes cut in the tip. This electrode is coupled with a rubber tube to an ordinary douche-can, while contact is made through a wire soldered to the electrode. A large indifferent electrode is placed behind the patient's back so that he lies on it. When only the lower part of the bowel is affected the patient is propped up, but for treating the whole large intestine he lies flat.

The quantity of current employed varies greatly and patients can stand as much as 150 ma. without any real pain, but a very emphatic warning must be given against using too large a current, as will be explained later. We do not, as a rule, exceed 50 or 60 ma., our practice being to find how much the patient can stand quite comfortably, and then to continue the treatment with about half that quantity. The current is turned on as the liquid flows into the bowel and a careful watch is kept on the milliampere-meter, and also on the patient's pulse, remembering that these patients are usually nervous and that it is as well to begin with small doses rather than with large until we know what the patient will stand. This is a most important point, because some patients experience a very serious degree of shock after the treatment, of which there is no warning at the time. It comes on about five minutes after the current is turned off, the patient suddenly showing signs of collapse, with cold clammy sweat, vomiting and a weak thready pulse. It does not occur in all cases, perhaps in half, and we have seen it in both men and women. We do not know what

the cause is, but it can be avoided to some extent by giving an injection of morphia beforehand, using only small currents, and turning the current off very slowly. The treatment is on the ordinary lines adopted for shock, and our experience is that it passes off in a quarter to half an hour.

The treatment is continued for about ten minutes at first and lengthened out as tolerance is established. The tendency to shock becomes less marked as the treatment continues, and in some cases no shock is noted at all after the first two or three doses. Treatment is given twice a week at first, but afterwards only one dose a week is necessary. The bowel is voided of the solution as soon as the treatment is over.

The results of ionisation are certainly very satisfactory, provided the patient will tolerate the shock that occurs in such a large number of cases. Forewarned is forearmed, and if the patients know what to expect they are much more likely to persist in a treatment that gives a better chance of success than any other of which we have experience, including irrigation through an appendicostomy.

Muscular Rheumatism. — The constant and sinusoidal currents, applied to the affected muscles either through the two- or four-cell bath, or still more beneficially by means of the roller electrode, brings about a rapid improvement. During the acute stage only the constant current with the anode connected to the painful part should be employed, but in chronic cases we have found the sinusoidal current of great use.

Nævi. — Since the introduction of carbonic acid snow electrolysis is less frequently employed in the treatment of nævi. We still find it of use, however, for the purpose of finishing off any small areas remaining after the carbon dioxide treatment. The electrolysis is carried out by means of a platinum needle, connected with the negative pole, thrust through the nævoid tissue. If the nævus is large, several needles connected alternately with the positive and negative poles and held in a special holder are employed, but of course this needs the assistance of an anæsthetic.

Capillary nævi, or port-wine marks, may also be treated in the same way with a very fine needle, but the treatment is very tedious and leaves a certain amount of scarring. We have also obtained some improvement in these cases by H.F. sparking from a vacuum electrode under an anæsthetic, but as yet there is no really satisfactory treatment for these cases, although both these methods bring about a certain amount of improvement.

Obesity.—The only form of electric treatment which appears to give satisfactory results in obesity is that afforded by the Bergonié apparatus. The outfit is a costly one, but the claims made on its behalf seem to be correspondingly strong. The apparatus consists essentially of an induction transformer designed to produce the "maximum of muscular contraction with the minimum of sensation"; the rate of interruption is capable of great modification, and is regulated by means of a metronome. The current is applied to the limbs through brass electrodes which are fitted in close contact with the skin.

We have no personal experience of this form of treatment, but according to the published results it produces a steady decrease in weight, accompanied by an improvement in the general health.

Papillomata and Warts. — The effect of the ionisation of warts with magnesium sulphate is very striking, the warts disappearing in the course of some three or four weeks after a single treatment. When the epithelium covering the warts is very dense it is advisable to prick it with a needle before ionisation is begun. The ions may be driven in through a pad soaked with the sulphate and connected with the positive pole, or the whole hand may be immersed in an arm bath containing a solution of the salt, after first pricking all the warts with a needle.

Paralysis.—During the acute stages of neuritis nothing more than a mild constant current should be used, but in the absence of acute symptoms the paralysed muscles may with advantage be treated with either the faradic or sinusoidal currents; these should be applied directly to the affected muscles through a pad or roller electrode.

Pruritus of the Anus or Vulva.—These conditions can nearly always be relieved by mild sparking from the H.F. vacuum electrode. We have also obtained very good results with X-ray treatment.

Rheumatoid Arthritis. — Electricity is a very valuable therapeutic agent in rheumatoid arthritis. When a single joint is affected the current may be applied locally by means of pads shaped to the part, or through the two- or four-cell bath when many joints are involved. A combination of the galvanic and sinusoidal currents may be used, or ionisation may be employed; in the latter case the pads are soaked in a solution of iodide or salicylate of soda and connected with the negative pole, or the salt may be dissolved in the water used for the baths. The theory is that the galvanic current sets up ionic changes in all the tissues through which it passes, while the effect of the sinusoidal current is to cause fibrillary muscular contractions which promote the circulation and help in removing the waste products that have been

liberated by means of the ionisation. But we believe that the improvement is due chiefly to the improved circulation.

It should be noted that in the majority of cases the first few treatments bring about no amelioration in the symptoms, and may actually make the condition temporarily worse, but these are the cases which usually give the best results in the end.

Rodent Ulcer.—During recent years X-rays, radium, carbon dioxide snow and ionisation have been introduced as alternatives to excision, and in reasonably early cases they are all very successful methods of treatment. They all have the disadvantage, however, of being comparatively useless when bone or cartilage is involved.

The advantages of ionisation over the other methods enumerated are the simplicity and ease with which it may be performed, and the precision with which the disease may be attacked. It is therefore by far the best method to adopt when the disease is in a difficult position to treat, such as the margin of the eyelid. The treatment is carried out by placing several layers of lint soaked in a 2 per cent. solution of zinc sulphate over the ulcer; a zinc electrode connected with the positive pole is pressed upon the lint, and a current of not less than three milliamperes per square centimetre of surface under treatment is passed for from twenty to thirty minutes. When the treatment is complete the surface of the ulcer should become coated with a dead-white layer. Owing to the importance of using a sufficiently large current to drive the zinc ions effectively into the diseased tissue we prefer to carry out the operation under light anæsthesia, especially when the edges of the ulcer are much thickened, as in this case it is advisable to pierce them with a zinc needle in order to destroy the deeper parts.

Provided that the disease has not extended to the bone or cartilage, as we have already said, zinc ionisation is a very satisfactory method of treating rodent ulcer, and a cure can be relied upon in the majority of cases. The cosmetic results are also better than with any other method except carbon dioxide snow.

Sciatica. — Sciatica frequently proves very intractable to ordinary methods of treatment, and some form of electric treatment is often of service in such cases. We have seen good results from the use of the Schnee foot-baths, the anode being connected with the painful limb, and also from the application of the roller electrode. If preferred, ionisation with sodium salicylate (2 per cent., negative pole) may be tried, and is often successful; pads soaked in the solution are applied to the course of the sciatic nerve, and large currents are employed. Recently, however, we have been successful with X-ray treatment in these cases.

Superfluous Hairs.—The treatment of hypertrichosis by electrolysis is a tedious business, as each separate hair has to be attacked separately. The needle must be passed right into the hair follicle, and no attempt must be made to extract the hair until the follicle is completely destroyed; this requires fully a minute, although the hair is easily pulled out at the end of about thirty seconds. The operation is a little painful, but an anæsthetic is not required. Not more than a dozen hairs should be removed at one sitting.

This method of treatment is a successful one of getting rid of the disfigurement, but requires a good deal of patience and not a little fortitude on the part of the patient. There is always regrowth of some of the hairs, even when the greatest care is taken to destroy the follicles, and these will necessitate further treatment.

Ulcers.—Chronic (non-malignant) ulcers may be treated by ionisation of zinc or copper. In either case a 2 or 4 per cent. solution of the sulphate is used, and is applied through pads backed by an electrode of the same metal. The effect of the ionisation is to make the surface cleaner and to promote healing. In varicose ulcers it is often very successful.

CLIMATOLOGY AND BALNEOTHERAPY

Climate as a means of treating disease has been utilised from the earliest times, and an enormous mass of literature has grown up upon the subject. From the present standpoint, however, the question has to be largely reconsidered. The virtual goal of all climatic treatment in the past was the cure or alleviation of phthisis. In recent years the introduction and universal adoption of the sanatorium method of treatment have practically relegated climate to a very minor position in the treatment of this disease. There will always remain a certain percentage of cases in which sanatorium treatment can be reinforced and often led to a successful issue by a change of climate. But at the most these cases will bear a small proportion to the total, and the clinical rules and cautions which fill the works of ten or twenty years ago need not detain us here. The aim of the present article is to describe, in brief, those regions which experience has shown to be of value and to indicate the diseases which are likely to benefit most from a stay in any given locality. Change of air may affect its object in two ways, on the one hand by removing the patient from conditions which produce and prolong his morbid state, as when a bronchitic

subject is removed from the fogs of London, on the other, when some definite physiological effect is sought, as when the jaded worker is sent to the bracing air of the Alps. Actually the effects are largely intertwined one with the other. For practical purposes climates for the invalid had best be considered as regards the districts which are most frequented than from purely geographical features. We may therefore consider—

The Climate of the Swiss Alps.
The Climate of Egypt.
The Climate of the Mediterranean Coast.
Home Climates.

The Swiss Alps.—The main features of such climates are low barometric pressure, and great diathermancy of the sun's rays. In winter, when once the snow has fallen, the air is singularly still, cloud is rare, and fog entirely absent. Owing to the sparse population and the presence of snow through a greater part of the year, the air is singularly free from impurities. The cold is in winter considerable; in Davos, for instance, the mean temperature is 18·6 in January and 29·3 in November, while the relative humidity varies from 79 to 84 per cent. In the still clear air of the Alps this considerable degree of cold is only felt as a pleasurable tonic. The physiological effects of the climate are in the first place those of altitude, as evidenced by breathlessness and rapid pulse, notably increased on exertion, headache, and often insomnia. Given that the individual has adequate powers of accommodation, the pulse within a few days becomes slower and firmer, the respirations deeper. Further, both the hæmoglobin and the corpuscles tend to increase, and the amount of water and CO_2 exhaled from the lungs is increased, notably so during the winter months. Other than these mechanical effects of diminished pressure the dry cold air produces a very marked influence on appetite and digestion, which are both improved, with a concomitant increase of nervous energy. These symptoms indicate a marked stimulus to metabolism, both through circulatory changes and by way of direct nervous stimulation. The therapeutic benefit to be gained depends on the patient's power of response to stimulus. With sound heart muscle, elastic arteries, and no marked toxæmia, nothing but good can result from a sojourn in the Alps in a very wide variety of ailments. The power of bearing cold can best be judged from the circulation: persons with cold hands and feet, with high blood pressure, or above all, with a ventricle beginning to fail behind old-standing high tension, rarely get benefit. The local physicians have long noted that patients with very rigid chest walls rarely can bear the cold of an Alpine winter. But given that the patient has the necessary natural caloric and sufficiently elastic arteries to emerge successfully from the trial of accommodation, the good to be obtained is very great. The clinical features of the cases of phthisis which are most suitable we shall refer to later. But for cases of bronchitis occurring in middle life, when degenerative changes are only just beginning, a sojourn may entirely obviate drifting into a chronic condition. Conditions of neurasthenia due to overwork derive the greatest benefit. In enumerating the individual resorts, it would seem advisable only to mention those to which invalids in the main resort, rather than the numerous centres devoted entirely to winter sports. Davos, 5200 ft., less windy, but not so sunny as some others, is probably the best equipped of all the resorts for the treatment of serious cases. St. Moritz, 6000 ft., is more sunny, but with greater exposure to wind. The other resorts in the Engadine, Pontresina, Samaden, Sils Maria, Maloya, present certain slight differences one from the other, but the main climatic conditions are the same. Arosa, 6100 ft., a very sheltered spot, with a large proportion of sunlight, is admirably equipped for the treatment of phthisis. In French Switzerland, Leysin, 4712 ft., above Aigle, sheltered from the wind with a sunny outlook, has great merits. Caux, 3580 ft., above Montreux, Les Avants, 3290 ft., and Château d'Œx, 3650 ft. all being better adapted for patients who are unable to bear the more exacting physical demands of the higher levels.

A series of lower resorts, such as Evian, Montreux, Glion, Territet, may be mentioned. Situated on the shore of Lake Leman, they are fairly sunny and free from fog, and form ideal spring and autumn halting-places, and have the further advantage that they are within easy reach of mountain stations of almost every altitude. Meran, with Obermais, in Tyrol, at an elevation of 1000 ft., is also a sunny and bracing spring and autumn resort.

Allied to the climate of the Swiss Alps are the resorts of the Rocky Mountains, but they have comparatively few sanatoria, and the chance of an invalid earning a living there is infinitely more precarious than at home.

Egypt.—The climate of Egypt, although it is only available for a few months in winter, is one of the most delightful in the world. Warm days, with constant sunshine, no mist nor fog, and practically no rain, and a very dry atmosphere, constitute an almost ideal climate for those of low vitality. The only drawbacks are the contrast of sun and shade, and winds—the cold northerly wind and the Khansin, a very enervating southerly wind—and the discomforts of an occasional dust-storm. Cairo is too large a

town for invalids other than jaded or neurasthenic patients; for them the changing scenes of an entirely new world provide a wholesome stimulus. Mena House, near the Pyramids, has a charming climate up to April. Helouan, situated in the desert sixteen miles from Cairo, with sulphur springs and good bathing accommodation, affords all the advantages of desert air, coupled with the unique possibility of a bath cure during the winter months. Luxor, 450 miles south of Cairo, is warmer and drier than Lower Egypt. Assouan, again, at the first cataract, is still warmer than Luxor, and, further on, Khartoum is warmer still. Upper Egypt though warmer is available for a shorter time. Practically the bulk of invalids follow the season from Lower to Upper Egypt and back again as the sun gains in power. Another charming method of enjoying the climate is the Nile steamer or the more costly and luxurious dahabeah.

Rheumatoid arthritis, bronchitis, renal and heart diseases, probably find the best environment in the world in Egypt. The calls on all the functions of the body are reduced to a low ebb, and the feeble powers of the old or weakly are conserved.

The Mediterranean Coast.—The seaboard of the Mediterranean presents a variety of climates —of these the Riviera, both from its remarkable natural features and great popularity, may be considered first. A gigantic undercliff was Henry Bennett's description of this region, and an apter phrase was never coined. A narrow strip of land, from one to five miles in width, bordered on the one side by the sea and on the other by mountains which rise steeply to a height of 1500–2000 ft. and pass backwards tier after tier to the main chain of the Alps. With minor variations this configuration stretches from Toulon to Spezzia, and it is to this mountain barrier that the peculiar features of the climate are due. Each town lying under the lee of the mountains, the shore bathed by a warm sea, while the bright sun not only warms it by day but insures the warmth being kept up at night by radiation. Such conditions confer warmth greater than less-sheltered regions in the same latitude. Fog is absent, and the rainfall, though almost equal to that of London, is concentrated into about a third of the number of rainy days, while the relative humidity varies from 65 to 75 per cent. as against 75 to 85 per cent. in London. But with these merits there are corresponding drawbacks, and the most notable of these are the cold winds which sweep through the passes of the mountains and become diverted in a direction parallel to the coast. A further danger to the invalid is the very marked difference between sun and shade temperature, and the very rapid cooling at sunset: a drop of nine degrees in five minutes may be experienced. The physiological effects are tonic, and to some extent exciting to the nervous system; digestion and appetite are generally improved, but sleep is apt to be interfered with. The virtues of the climate are, in the first place, that a very diminished call is made on the power of reaction, and in the second, that absence of fog and dryness of the air exercise a beneficial effect on any bronchial or pulmonary trouble. The best months are from mid-October to mid-May; after this the heat becomes too great for invalids to derive benefit. The individual resorts differ in the character of their climate, largely as they are nearer or farther from the sea, or as mountains are immediately behind them or at a greater distance inland. Hyères, near Toulon, the most westerly, is situated some miles from the sea and at some distance from the mountains. St. Raphael and Valescure, the former situated on the seashore, the latter some two miles inland amongst the pines, are bracing and well adapted to the vigorous. Cannes, the most fashionable of all the resorts, stretches over a wide area, the mountains being some distance inland. Consequently it is colder than some other resorts, but definitely more bracing. Grasse, further back in the hills, at an elevation of 1500 ft., forms an admirable place of change for those who tend to flag at the lower levels. Thorenc, 4000 ft., is of great value as an accessible summer resort. Nice, a large town with the charming suburb of Cimiez on a spur of the mountains, is essentially a pleasure rather than a health resort. Beaulieu and Monte Carlo are very sheltered and sunny; at Mentone, the cradle of the reputation of the Riviera, the East Bay is the most sheltered and warmest spot on the coast. Then, crossing the frontier into Italy, we come to Bordighera, more open and colder, and more bracing. Further on, San Remo, only slightly colder than the East Bay of Mentone. Alassio, bracing and more rural in its surroundings. Beyond Genoa the climate changes and is more humid and sedative. Pegli, Rapallo and Santa Margherita are all sheltered and sunny. Florence and Rome may be mentioned, but are in no sense climates for invalids other than the attractions afforded by a considerable degree of sunshine and wealth of artistic treasures. Naples, with Sorrento and a few stations along the adjacent coast, is warm though variable and rainy, and hardly adapted for invalids. Sicily is warm, somewhat wet and extremely variable, bright sunshine, cold winds and rainstorms often succeeding each other. The natural beauties and relics of the past make it an ideal resort for the elderly or the neurasthenic. The island of Corsica is warmer than the Riviera and some-

what more humid; the town of Ajaccio is sheltered, and forms an attractive and healthy winter station for bronchial cases.

Algiers is warmer than the Riviera, the mean winter temperature being 57·3, there is less contrast of sun and shade temperature, and the rainfall is greater, amounting to some forty inches. Bronchial and asthmatic cases do well there. Mustapha Superior, a suburb of Algiers, has good accommodation. A more bracing station is Hamam R'Irha, situated at an elevation of 2000 ft. in the lesser Atlas Mountains. At Biskra, again, a day's railway journey inland, the full benefit of desert air is obtained; it is therefore well adapted for rheumatic cases. Further westward, Tangiers, which is more under the influence of the Atlantic than that of the Mediterranean. Gibraltar, with the new resort of Algeciras over the Spanish lines, is sunny but windswept, and has the humid character of the Atlantic seaboard. Malaga, on the south-eastern coast of Spain, is warm and dry and well protected, but the accommodation is poor. The Balearic Islands have a very warm, dry and bracing climate, with fair accommodation. Madeira, in the Atlantic, has a remarkably equable temperature. The mean winter temperature being 61 and summer 69, it is admirably suited to persons of low vitality. The Canary Islands, Teneriffe and Grand Canary resemble Madeira in equality, but are drier and more bracing.

A few other localities in the south of France may be mentioned here. Biarritz, situated south of Bayonne, is sunny and experiences all the bracing influence of the Atlantic. Arcachon, south of Bordeaux and on the confines of the Landes, surrounded by pine woods, is warm, moist and remarkably sedative. Pau, between Bayonne and Toulouse, is warm, sunny and unusually windless; it is well suited for bronchial and many neurasthenic cases; the climate is notably sedative. Vernet les Bains, thirty miles from Perpignan, near the Spanish frontier, with its sulphur springs of various temperatures, has a dry and mild climate, which enables bath treatment to be carried on during the winter months.

The Health Resorts of the British Isles may be divided into the tonic or stimulating and the sedative, warm and sheltered. The bracing seaside resorts are situated for the most part on the East Coast, which is also the driest part of England. Margate, Broadstairs and Ramsgate are very bracing, and have acquired a well-deserved reputation for the beneficial effects of the climate on enlarged glands and surgical tuberculosis generally, as well as for debility of all kinds occurring in children. On the other side of the estuary of the Thames we come to Felixstowe, well protected and sunny; Aldeburgh, Lowestoft and Yarmouth. Cromer and Sheringham look due north and have a great reputation for the jaded and overworked who can stand strong air. Bridlington, Scarborough, Filey and Saltburn are somewhat damper than the Norfolk resorts. In Scotland Stonehaven and Nairn may be mentioned. Inland resorts of a bracing character which are adapted for those whom the sea affects injuriously, such as the gouty and those suffering from certain forms of skin disease and some cases of insomnia, are typified by Malvern and Ilkley in England, Braemar and Aviemore in Scotland. The more sedative and sheltered localities of the south are of great value as winter quarters for cases of bronchitis, heart disease, persons with impaired powers of locomotion and feeble vitality generally—Hastings and St. Leonards, Bexhill in Sussex; Bournemouth, warm and very sheltered, as is also Ventnor in the Isle of Wight. In the West country, Torquay, Sidmouth and Falmouth are warm and sheltered. Tunbridge Wells has great merits as a warm and sheltered inland resort, well adapted for the same class of case as Bournemouth, but which is injuriously affected by the sea. Taken as a whole, the British resorts lack the bright sunshine and dry air of many foreign places; but, on the other hand, they do not overstimulate the nervous system as is the case with many foreign places and they have the merit of being available all the year round. As Charles II said, one can pass more time out of doors in England than in any other country in the world.

Having described the principal regions which are sought in search of health, the diseases likely to be benefited may be considered individually. **Bronchitis** in its more usual form, when an increased tendency to catarrh and emphysema is a sign of tissue degeneration, is much benefited by a sojourn on the Riviera. The absence of fog and the possibility of open-air life not only allow the bronchial mucous membrane to recover to some extent its normal tone, but also check degeneration by diminishing the demands on metabolism. When the cough is dry, and expectoration scanty, Madeira, the Canary Islands, Algiers or Corsica are indicated. Winter cough beginning in early middle life is benefited far more by a sojourn in the Alps than anywhere else if the patient is sufficiently robust. Egypt, although available for a shorter period of the winter, is probably the best climate for the senile form.

Asthma is notoriously capricious, and has to be considered both from its nervous and bronchial aspect. Pure nervous asthma in a young adult is often strikingly benefited by a sojourn in the Alps or by treatment in the summer at Mont Dore (see later). For the more bronchial type, the Riviera at some

elevation from the sea or Egypt is more suitable.

The chief influence of climate in **diseases of the heart** lies in the avoidance of bronchitis or broncho-pneumonia, consequently Egypt, Algiers or the Riviera are indicated. High altitudes are in the main contra-indicated, though some cases of bradycardia in early middle life are strikingly benefited by a graduated ascent to a high altitude, and by carefully regulated exercise. Most cases of heart disease are injuriously affected by a sea voyage.

Rheumatoid arthritis derives more benefit from a winter spent in Egypt than any other form of climatic treatment. Failing this the Riviera or Algiers, where the open-air life improves general nutrition, and the rheumatic pains are generally benefited by the dry atmosphere. At home, the dry air of the East Coast gives the best results.

Gout is benefited by a warm climate, whereby the strain on the kidneys is relieved, while general metabolism is improved by the open-air life. Egypt, the Riviera or Algiers are the most favoured resorts. In our own climate gouty conditions are apt to be aggravated by the sea air.

Diseases of the kidneys derive marked benefit from residence in a warm climate. Cases of nephritis, whether parenchymatous or interstitial, often show the most surprising improvement. The increased action of the skin has a notable effect both on the amount of albumen and the general symptoms, such as headache and dyspepsia. Egypt, the Riviera, Algiers, and for patients who bear voyages well the Canary Islands or Madeira are the most suitable places. It is essential that the sojourn should be made as long as possible, and that the return to England should be made sufficiently late. No class of disease is more adversely affected by sudden change from warmth to cold.

Diseases of the Nervous System.— Organic diseases such as tabes or sclerosis only derive benefit in so far as an open life is possible for them in a warm climate, such as Egypt, Algiers or the Riviera.

Hemiplegia equally benefits in as far as a warm climate benefits the concomitant arterial degeneration.

The sufferers from that medley of functional morbid conditions which are for convenience grouped under the heading of **neurasthenia,** are for ever trying change of climate as a refuge from their miseries. When the circulation is good and the patient vigorous, he should be sent to the Alps, unless insomnia is a marked symptom: given that he sleeps and can and will take exercise, the constant stimulus of air and altitude will do more to restore him to health than any other form of treatment. In cases where the hands and feet are cold and the blood pressure low, Egypt or the Riviera, Rome, Florence or Sicily, may be tried, but here again it is essential that insomnia is not a marked symptom. Then the artistic treasures of Italian cities or the gorgeous colouring of the East may give them fresh ideas and break the habit of what the French describe as "listening to themselves live." Where insomnia is a marked symptom Pau or Arcachon may be tried, otherwise it is better to try one of the English resorts, the East Coast in the summer and one of the southern or western resorts in winter. Malvern and Ilkley and Braemar are also of great service in such cases. A word of caution must be given against sending these cases for sea voyages should they show that not uncommon symptom unreasoning terror, for the fear of drowning aggravates the situation: the writer has seen the most pathetic instances of demoralisation occurring in mid-ocean. Venice and the Italian lakes at certain seasons are of the greatest value in that form of neurasthenia engendered by definite hard work.

Neuralgia and Migraine are benefited by a dry and warm climate such as Egypt or the Riviera. They rarely benefit by high altitudes.

Diseases of Digestion are benefited by change of climate in so far as they depend on some secretory or motor failure of nervous origin. Flatulent dyspepsia often shows striking improvement at high altitudes. Dyspepsia due to slow digestion is also benefited by a sojourn in Rome or Florence, the Riviera. Mucous colitis is benefited by removal to a warm climate—preferably Egypt or the Riviera—where intestinal spasm, and dyspepsia are notably lessened.

The climatic treatment of **phthisis** at the present time presents considerable difficulties, as outside the admirable sanatoria at Davos, Arosa and Leysin the difficulty of finding accommodation is very considerable. Early cases with limited disease who make but slight progress in sanatoria at home may derive increased benefit from going to the Alps. It is not necessary here to indicate the class of case which will be suitable or unsuitable, since in the majority of instances the patient will have undergone a period of probation at a sanatorium. Cases which have become partially arrested or cannot bear the cold of open-air life in England and those with dilated bronchi and constant attacks of bronchitis derive the greatest benefit from a sojourn in Egypt or the Riviera. California affords a good climate for partially arrested and fibroid cases, but it must be borne in mind that the chance of earning a livelihood is even slighter than at home. Bronchiectatic phthisis derives great

benefit from the Alps, or, if complicated with much general bronchitis, from Egypt or the Riviera.

The advanced cases should never be sent away unless with full knowledge of the probable result, and with means for every comfort. Then Madeira, Egypt or the Riviera may be tried. But, as Sir Thomas Browne said, "he found the most healthful air of little effect where death had set her broad arrow."

The climatic treatment of **diseases of the throat** is in the main directed to cases of simple pharyngitis or laryngitis in which removal from adverse conditions such as damp or fog will of themselves effect a cure. Egypt or the Riviera, or, where there is much dry cough, Madeira, the Canaries or Corsica are preferable.

Finally, we have to consider how far those slow degenerative changes which we call growing old can be alleviated by change of climate. A man is as old as his arteries, and when the effects of high blood pressure and subsequent arteriosclerosis begin to make themselves felt, whether in wind or limb or instability of nervous system, the time has come to lessen the stimuli to increased work. The whole subject has been treated with consummate literary skill by Dr. King Chambers. The practical point is that when degenerative changes become manifest the patient should be removed to a warmer climate for the winter, Egypt, Algiers, or the Riviera. Probably the open-air life and diminished calls on his metabolism will enable him to lead a moderately active life for some years. With increasing feebleness a journey abroad will be less and less advisable, but in the mild atmosphere of Bournemouth, Torquay, or Falmouth, he may still maintain a fairly active life for many years beyond his allotted span. M. G. F.

HYDROLOGY

By the term Hydrology we mean the drinking of waters more or less impregnated with mineral substances at their fountain-head. A further development of this process is bathing in the waters, or their application as douches, sprays or enemata. And yet a third is the application of other substances such as mud, peat or fungi to the surface of the body. In the first place it must be conceded that the effect on metabolism which is observed from drinking waters is in no sense proportional or, indeed, comparable to the therapeutic action of the salts which they contain. The discovery of radium has to some extent cleared the ground and given scientific sanction to the old view that a natural mineral water was a thing *sui generis*, and to be used according to the traditions of experience rather than in conformity with the theories of pharmacy. Within the scope of this article a classification of waters according to their chemical characters would serve no useful purpose. Practically, we know that some are purgative and diuretic, others contain sulphur, iron, or arsenic, while others again, of great value, would appear to be natural hot water containing very little in the way of chemical constituents. On the other hand, the higher the proportion of chemical constituents, the more potent as a rule the effect of the water, each in its own way according to its chemical character. The most feasible plan of indicating the effects of mineral waters would appear to be to discuss them under the heads of individual diseases for which they have been found to be indicated. Baths may act in many ways, either by their natural action upon the skin as sulphur baths in eczema, or, from the gas which they contain by its mechanical effect in dilating the capillaries of the skin. To a large extent baths are used in the form of douches, which enable forcible massage to be used with less pain to the patient and consequent relief to stiffness and pain about inflamed joints or muscles. Immersion baths of peat or mud are of great value in soothing the pain and lessening the induration about old inflammations such as sciatica, lumbago and neuritis, or old pelvic and peritoneal adhesions. Different mineral waters may be pulverised and used as sprays for the throat, nose or ear, clearing away adherent mucus, and paving the way for the mucous membrane to resume a more healthful vascular condition. In like manner, by their carefully regulated use as enemata, the lower bowel may be cleared of mucus and intoxication of the whole system lessened. The vagina may also be markedly benefited by immersion in a bath with a speculum *in situ*. Many spas have grown to great repute for the treatment of particular maladies largely owing to the shrewdness and ingenuity of the local doctors in devising fresh methods of local hydrotherapeutic treatment. In discussing the individual classes of disease it is only possible to mention the main spas for which each is suitable.

Disorders of Digestion. — Spa treatment in these affections is to a large extent the treatment of abdominal plethora, the result of a succession of feasts coupled with too little exercise which the fashionable season of every capital in Europe is apt to engender. Homburg, with its mildly purgative waters and well-managed régime, Marienbad, Kissingen in Germany, Vichy in France enjoy a well-deserved reputation. In England Llandrindod, Harrogate or Leamington, and in Switzerland the charming mountain resort of Tarasp may be recommended. For the dyspepsia of anæmic

young women, Schwalbach or St. Moritz are indicated.

Diseases of the Liver.—Cholelithiasis, and portal plethora, notably that produced by residence in the tropics, derive great benefit from the natural hot sulphate of soda springs of Carlsbad. Vichy or Brides in Savoy; Leamington, Llandrindrod, Buxton or Harrogate in England; and Strathpeffer in Scotland give good results.

Diseases of the Intestines.—At Plombières was first instituted a definite plan of treatment for washing out the colon by carefully arranged machinery, aided by the use of under-water massage to the abdomen to lessen spasm. The success which attended this attempt to treat a disease previously considered hopeless has led to its adoption at many other spas, such as Luchon, Vichy, Harrogate, Buxton and Bath. The results obtained have certainly justified its adoption.

Diseases of Urinary Organs.—For gravel and different forms of nephrolithiasis, Contrexéville, and Vittel in the Vosges, have attained the greatest celebrity; Monte Catini in Tuscany also is of distinct value. For diseases of the bladder and prostate, Wildungen in Pyrmont has a great reputation; the waters are earthy and are drunk in large quantities, but not a little of its undoubted success is due to the skill of the surgeons who practise there.

Diseases of the Circulation.—In the first rank comes Nauheim, with its baths charged to a high degree with natural carbonic acid gas. The value of the treatment in cases of valvular disease and dilatation due to high tension is undoubted. Most spas or therapeutic institutions now have installed baths impregnated with artificial carbonic acid gas. These have decided value, notably in anginal or severe cases for which a long journey would be too risky. It must be admitted, however, that for earlier cases the natural waters are markedly superior in their action to the artificial ones. In France, Royat possesses naturally aerated waters, which are used in much the same way as at Nauheim.

Diseases of the Respiratory System.—The spa treatment of these diseases consists essentially in the administration of sprays or nasal douches of mineral waters, whereby the pharyngeal or bronchial mucous membrane is cleared from mucus and stimulated. At Ems the system is very carefully carried out, machine-driven sprays of varying strength and fineness are applied to the throat or nose, while supplementary pneumatic machines are used to increase the play of the lungs and rectify the evil effects of emphysema. The effects of this treatment, combined with the interdiction of all tobacco and the undoubted value of the waters, have a most marked effect on cases of bronchitis, asthma and pharyngitis. Cauterets, in the Pyrenees, has somewhat the same system with sulphur water, and at Mont Dore, in Auvergne, the sprays of alkaline waters are combined with the drinking of arsenical waters. The same system of inhalation has been installed at Bath, Buxton and Harrogate. At Salso Maggiore in Lombardy, inhalations of bromo-iodine water are given; the patients also sit for a considerable time in an atmosphere saturated with the spray of this water.

Diseases of Women.—The effects of past pelvic inflammation were first treated at Franzensbad by peat baths with marked success, a method which has been copied at many other spas. Considerable success has resulted from the Bromo-Iodine baths at Woodhall Spa, Kreutznach, and Salso Maggiore in cases of simple congestion.

Diseases of the Joints.—The spa treatment of gout resolves itself into either relieving plethora by purgative and diuretic waters, or the use of sulphur waters which are claimed to have a direct effect on metabolism. For the former purpose Homburg, Carlsbad, Tarasp, Kissingen and Vichy are all of value. In the second category, in which the arthritic symptoms predominate over the digestive ones, the Pyrenean springs have considerable merits, the principal spas, Luchon and Cauterets, having admirable installations. At home, Llandrindrod Wells, Harrogate and Strathpeffer, yield good results.

The variety of pathological conditions which for convenience may be grouped under the name rheumatoid arthritis, are benefited by spa treatment in a twofold manner, constitutional and local. In the first place the ingestion of waters lead to the elimination of waste products. In the second place various forms of local treatment have been evolved at different spas for the relief of pain and stiffness. Aix-les-Bains in Savoy early adopted the method of massage carried out under a stream of water, a system said to have been brought back from Egypt by Napoleon's troops. The same method has been adopted at most spas which were resorted to for arthritis. In addition to Aix, Vichy, Baden-Baden, Schinznach in Switzerland may be mentioned. Bath has radio-active waters and a good winter climate, so that treatment can be carried out during the winter months. Other British resorts are Buxton, Harrogate, and Strathpeffer in Scotland. Another method of treatment is immersion in peat baths, which yields admirable results, notably in cases of sciatica. These originated at Franzensbad, but are used at Marienbad, Carlsbad, Strathpeffer, Harrogate, Llandrindod Wells and Buxton. Immersion in brine baths forms a valuable form of treatment at Droitwich, Reichenhall and other

spas. At Acqui, in Piedmont, the application of hot mud soaked in sulphur water, either to a single joint or to the whole body, produces good results.

Diseases of the Nervous System depend in the main on the treatment of some underlying constitutional condition. Headache and neuralgia is often cured by a course of sulphur waters. At Lannalou in France great relief is afforded to the pains of tabes from effervescent baths. The different forms of neuritis are best treated by the same methods as those applied to rheumatoid arthritis.

Diabetes and Glycosuria derive benefit from the waters of Neuenahr, and when due to gouty conditions from sulphur waters.

Diseases of the Skin are benefited on the one hand from the internal use of waters to lessen a gouty tendency, and on the other by prolonged immersion in baths of mineral water. Sulphur baths are the most generally useful, and those of Schinznach, Strathpeffer and Harrogate enjoy a well-deserved reputation. M. G. F.

TREATMENT OF ELEMENTARY SCHOOL CHILDREN

The Medical Inspection of Elementary School Children, although a natural corollary of Elementary Education, is only of recent and gradual growth. It was first necessitated by the provisions of the Special Schools Acts of 1893 and 1899, although two cities had previously appointed School Medical Officers, but it was only after the passage of the Elementary Education (Administrative Provisions) Act of 1907 that it became a compulsory duty of all Education Authorities to appoint School Medical Officers, and to carry out routine inspection of the school children. By the provisions of this Act, which came into force on the first of January, 1908, every child must be examined immediately before or as soon as possible after admission to school, and at such other times as the Board of Education may require. The present policy of the Board is to require also the examination of children shortly before they leave school and at an intermediate period, that is about the age of from eight to ten years. This Act also gives to the Local Education Authority "the power to make such arrangements as may be sanctioned by the Board of Education for attending to the health and physical condition of children educated in the public Elementary Schools," provided that they may encourage and assist the establishment or continuance of voluntary agencies to this end. This Act is therefore a very important one, for it is by its sanction that all medical treatment of school children is carried out by the Education Authorities.

Several other Acts of Parliament give powers which are important from the medical point of view. The Elementary Education (Blind and Deaf) Act of 1893 makes it compulsory upon all Education Authorities to provide accommodation for blind and deaf children between the ages of seven and sixteen in special schools. It also makes attendance at school on the part of these children compulsory. It is not sufficiently widely known amongst medical men that every deaf or blind child of poor family has a right to be educated. The Elementary Education (Defective and Epileptic) Act of 1899 permits a Local Education Authority to provide special accommodation in school for mentally and physically defective children and for epileptics. Such provision is not compulsory, but where it is provided the parents of a child who is alleged to be defective have the right to demand that he shall be medically examined with a view to admission to the special school, and children who are certified to be defective can be compelled to attend the school between the ages of seven and sixteen. Every child attending such a special school must be medically examined at least once a year.

One other Act requires mention. The Education (Provision of Meals) Act of 1906 gives the Education Authority the power to take steps to provide meals for children attending the Elementary Schools and to co-operate with any Committee that undertakes such provision. It also empowers them to spend money on providing meals up to the extent of a halfpenny rate, and requires that the cost of the meals so provided shall be recovered from the parent, unless the Authority are satisfied that the parent by reason of circumstances other than his own default is unable to pay the amount.

In addition to these Acts which deal directly with Educational matters, the Local Education Authority can utilise the general clauses of the Children's Act of 1908 and other similar Acts in dealing with neglected and verminous children.

The treatment of Elementary School children, then, includes general medical treatment provided for children in the Elementary Schools, the educational treatment of defective children, the feeding of children in school and the treatment of neglected and verminous children.

General Medical Treatment

Medical inspection in the Elementary Schools has brought out clearly the fact that there are several important groups of diseases and defects which are extremely common amongst school children, which have an important bearing upon the education and prospects of the child, and for which there is at present a very

inadequate organisation for treatment. These defects include defective vision, diseases of the throat, nose and ear, specially enlarged tonsils, adenoids and otorrhœa, ringworm and the commoner infectious skin complaints, *e. g.* impetigo and scabies, and dental decay. In addition, the slighter (postural) curvatures of the spine, and general anæmia and debility, whilst they need not prevent attendance at an Elementary School, have an important bearing upon regular school attendance and educational treatment.

It will be evident that treatment for these defects, requiring, as it may, expert examination, operation, and special methods such as the use of X-rays for ringworm, could only be obtained by the poor through the hospitals; and the amount of routine work thus thrown upon the hospitals as the result of school inspection very soon became burdensome. The Board of Education has, therefore, sanctioned various special methods whereby this treatment may be secured at the expense of the Local Education Authority. The two methods which have been chiefly utilised are the institution of special out-patient departments at the hospitals, and the establishment of School Clinics.

Special out-patient departments for the treatment of visual defects, diseases of the nose, throat and ear, and of skin diseases such as ringworm, have now been established by many hospitals. The arrangements made are that the clinic is held at a special time (not at the ordinary out-patient time), that a certain definite number of children are sent for examination or treatment on each day so set apart, the School Care Committee being responsible for this, and that a salary is paid by the Education Authority to the medical man doing the work, and a capitation grant to the hospital for each child so treated.

School Clinics, properly so-called, are established and paid for by the Local Education Authority, the medical officers of the clinic being appointed by that body and paid a salary. In some districts, however, the local members of the profession have preferred to attempt to keep this treatment at clinics under their own management. The clinic is then carried on by a local committee of medical men, who select and nominate the medical officers. The latter are paid a salary by the Local Education Authority, who also pay a capitation fee for each child treated to go towards the current expenses of the clinic. This latter system, while it is favoured by practitioners in many parts of the country, has been criticised by the Board of Education because it places the Treatment Clinics outside the direct control of the School Medical Officer for the district, and because by means of it school inspection and treatment are not very perfectly co-ordinated. It is at present recognised by the Board, but in the event of the latter withdrawing that recognition the Treatment Centres so established would have to be closed.

Diseases of the Eye.—Children are referred to the clinics from the schools on account of defective vision, squint, simple external diseases of the eye, and diseases of the lids. The standard of defective vision requiring treatment is usually taken as six-eighteenths or worse with either eye for children in the lower classes, and six-twelfths or worse with either eye for children in the upper classes. It is most important that the treatment thus arranged for children suffering from defective vision should not stop at the prescription of glasses. It is customary for an arrangement to be made whereby a spectacle maker attends at the clinic, and the Board of Education have sanctioned arrangements for the provision of spectacles by the Local Education Authority, provided that every possible endeavour has been made to obtain them by the parents, or through voluntary associations. Further, it is most important that the school teachers should see that the children wear the glasses provided, and arrangements should be made for the re-examination of the children at intervals. Except by the correction of defective vision in one or both eyes, little or no attempt has up to the present been made to treat squint in School Clinics. The other eye diseases treated are blepharitis and the simple forms of conjunctivitis. The more serious diseases of the eye have to be referred from the clinic to the hospitals.

Diseases of the Throat and Nose.—The large proportion of children treated under this heading suffer from nasal obstruction, most often as the result of adenoids. This condition is so frequent that the treatment of it constitutes a serious burden upon the hospital out-patient departments, and at the same time it is serious in its results both from the physical and from the educational point of view. The treatment of adenoids has therefore become a recognised function of the School Clinic. The removal of enlarged tonsils may be grouped with it. These operative procedures of course necessitate a theatre, a waiting-room and a recovery-room. A surgeon, anæsthetist and two nurses can comfortably manage about ten operations in an afternoon in a clinic; in a hospital, with ample accommodation and more nurses, fifteen to twenty can be performed. It is most important where adenoid operations are being performed that one or two beds should be available, so that children can be kept under observation for a night if necessary.

The treatment of adenoids is not completed

with the operation. It is most necessary that proper methods of breathing should afterwards be taught. The children must be collected together either at school or at the clinic for daily breathing drill. This should begin with the clearance of the nose by proper use of the handkerchief; breathing exercises, both simple and combined with arm and trunk movements, being then carried out for ten to fifteen minutes. In some cases, when the chest is flat or deformed, passive chest expansion movements combined with deep breathing exercises are also desirable.

Diseases of the Ear.—Under this heading practically only cases of chronic suppurative otitis media come under treatment. These are very frequent among school children, and the ordinary hospital out-patient treatment, consisting of the prescription of a lotion to be used at home for syringing or for instillation, has been proved to be very inefficient. Yet it is known that a large proportion of such cases can be completely cured by methods of ordinary cleanliness. The defect is not in the method of treatment but in the thoroughness with which it is carried out at home. If the clinic is to treat these cases satisfactorily, the syringing, etc., must be carried out by a nurse, either at the clinic itself or by the nurses visiting the children in their homes. Both these methods have been tried and have proved highly satisfactory. Cases which do not respond to such treatment, thoroughly carried out for three months, had better be referred to a hospital, as more drastic steps will probably be required.

Diseases of the Skin.—The most important of these is ringworm, which, owing to the difficulty of securing a complete cure has in the past been responsible for frequent prolonged absences from school. It has now been amply demonstrated that X-ray treatment is the most efficacious and in the end the most economical method. In Bradford it has been found that by this means the period of treatment is reduced on an average to 30 days, and the absence from school to 35 days. Treatment by the older methods resulted in an average loss of school attendance of 287 days. X-ray treatment properly carried out is absolutely safe, the scalp is free from infection as soon as the hair has fallen out, and the hair should be well grown again at the end of three months.

The other skin diseases treated consist of scabies, impetigo and similar infectious complaints. Their treatment requires no special comment.

Spinal Curvatures.—Those who have systematically examined a large series of school children for spinal curvatures have found that from 16 to 25 per cent. of the children could be classed as showing some degree of curvature. Only a very small proportion of these showed a structural curve, the large majority showed only a postural deformity, capable of correction when the child was shown how to stand or sit correctly. It is these common postural curves which require treatment in school or in the clinic; the structural curves are unsuitable for such treatment. Two methods are in use for organising this treatment. The first is by means of a special exercise class held daily for not more than ten children at a time in the school. The second is by similar but perhaps more individual exercise treatment at the clinic. In the first case the exercises must be carried out by one of the school teachers, who must first be specially instructed. In the second case it will probably be possible to secure the services of a trained instructress. The simple method of ascertaining in each case what type of treatment is required is to determine whether the posture assumed by the spine is one which the normal spine can assume. If it is not, then the curve is a structural one, and it will be more satisfactory to recommend hospital treatment. If the curve is one which can be imitated in the normal spine, it must then be determined whether the child by careful instruction can be induced to hold himself in a correct attitude. If he can, then class exercises carried out daily in school will be effectual; if, however, he cannot manage to get into a good attitude it will be better for a time at least to give him individual exercises in the clinic.

Dental Disease.—Medical inspection has amply demonstrated the great prevalence and importance of dental decay amongst children. The ways of combating this are briefly three: first, by altering by educational means the diet in infancy and early childhood and rendering this more suitable; secondly, by encouraging the use of the toothbrush amongst Elementary School children, and thirdly, by arresting dental decay at its commencement. The last necessitates the establishment of Dental Clinics, for there are, as a rule, no hospitals to deal with the work, and the payment of proper fees to a dentist is quite beyond the means of the parents of the average child. These clinics are still in the experimental stage, and to establish a complete system of treatment on these lines will necessitate a large organisation and will be a heavy expense. The experience so far obtained indicates that the treatment should be begun early, if possible before the age of six, that it should be preventive, temporary teeth being extracted whenever necessary, but permanent teeth preserved and filled, and that every child that has once been treated should be re-examined at regular intervals so that further trouble may be detected and treated in its early stages.

A Dental Clinic requires, of course, the

ordinary dental equipment for extractions and fillings. A dentist working five days a week may be expected to deal with a school population of 3000 to 4000 children.

Educational Treatment of Special Classes of Children

The classes of the blind and deaf children require only very brief mention. The definition of suitability for a special school is that the child is so blind as to be incapable of instruction through the ordinary visual channels, or so deaf as to be incapable of instruction through the ordinary auditory channels. There remain, however, a considerable class of children whose vision or hearing is so defective as to render them incapable of keeping pace with normal children, although they cannot be classed as completely blind or deaf. In the case of the partially blind also there is undoubtedly a risk that the strain of an ordinary school may further injure the eyesight and lead to complete blindness. Education authorities in certain large towns, recognising the impossibility of educating such children in the ordinary schools, have established special classes for the partially blind and partially deaf children.

Mentally Defective Children. — Mental defect in the educational sense indicates that whilst there is so low a mental status that the child cannot be educated with normal children, yet he is capable of attaining a certain degree of education, sufficient to give him a reasonable chance of becoming self-supporting; that is to say, he is not an imbecile or an idiot. The diagnosis of mental defect is often very difficult, particularly so in children who have been out of school and have never been taught. In addition to the consideration of the family history, medical and educational history and physical condition of the child, a careful mental examination is required. This should include investigation of the organs of sense, power of observation, memory, concentration and judgment, temperament, power of control and moral characteristics. Further, the educational attainments must be tested and considered in comparison with the normal, bearing in mind his age and his opportunities to learn. Various schemes of examination have been suggested. Of these the best known are the Binet tests. If a child is unable to respond to these tests as drawn up for an age two years less than his own, he is presumably mentally defective. One word of caution is necessary; these tests are drawn up on the supposition that they will be new to the child. As they get to be known they are used by the school teachers in testing the children in the Elementary Schools, the children learn them, and their value as a test of mental defect diminishes.

There can be no hard-and-fast line of mental defect. There must always be a proportion of dull backward children, and of children who are backward probably as the result of lack of educational facilities. For these there is an urgent need of intermediate schools or intermediate classes, into which the children can be drafted from the Elementary Schools, and in which their progress under more individual instruction can be noted. These classes give such backward children their chance of regaining their place in school, and render the diagnosis of doubtful cases of mental defect much more easy.

Physically Defective Children. — The term "physically defective" includes children who are crippled by tuberculous disease of the bones and joints, by paralysis and in other ways; chronic invalids, specially those suffering from heart disease and chorea, and anæmic debilitated children. Children who suffer from pulmonary tuberculosis may also be included as a special group.

A number of different classes of schools have been provided.

1. Resident Hospital Schools.
2. Resident Sanatorium Schools.
3. Country Recovery Schools.
4. Non-resident Day Schools.
5. Open-air Schools.
6. Trade Schools, Resident or Non-resident.

All these except the day schools necessarily include treatment for the physical condition of the children. Open-air schools require special mention. They are specially suitable for anæmic debilitated children, those suffering from slight heart lesions, and convalescent (non-infectious) cases of pulmonary tuberculosis.

The holding of the classes in the open air is only one part of the special treatment given in these schools. In addition the hours are long, from nine in the morning until six or later in the evening. Three meals, breakfast, dinner and tea, are arranged in school, a two-hours sleep is taken in the afternoon, and every child is bathed in school once or twice a week. The effect of these schools is therefore to put the children under good hygienic conditions for nine hours out of each twenty-four.

Treatment of Dirty and Verminous Children.— Two chief methods are utilised for endeavouring to improve the cleanliness of children. The first is to serve notices upon the parents stating in what respects the children are dirty, and directing how they may be cleansed. After two such notices, if no efforts to secure greater cleanliness have been made, the child is excluded and the parents prosecuted for not sending him to school in a fit condition. In the second method after the first notice warning the parents, the

child may be taken by a person authorised by the Local Education Authority, usually a school nurse, to a cleansing station and the child and his clothing cleansed. It is as well that the Sanitary Authority should at the same time cleanse the home.

School baths may be provided by the Education Authorities. On the Continent they are numerous; in England they are at present few, but are increasing. R. C. E.

TREATMENT BY MASSAGE, MOVEMENTS AND PHYSICAL EXERCISES

Massage consists in the treatment of some part of the body by friction, pressure or kneading. In ordinary massage these manipulations are carried out by the hand in various ways, but similar effects can be obtained by means of certain mechanical contrivances such as some forms of Zander apparatus, or by an electrically driven machine.

Methods of Manual Massage.—The ordinary methods of manual massage are—

1. *Effleurage*, i. e. stroking with the palm of one or both hands, or with the thumb and tips of the fingers. The stroking is always carried out from the periphery towards the centre, in the direction of the flow of venous blood; its effect is to increase this venous flow and also to increase absorption through the lymphatics, so that it assists in getting rid of inflammatory or traumatic effusions. Stroking has also a slight local analgesic effect.

2. *Frictions*, i. e. firm rubbing movements carried out in circles with the thumb or with the tips of the fingers. The effect is again chiefly to improve the local circulation, but friction has a deeper action than stroking, and to some extent indurated tissues and adhesions can be softened and stretched by deep friction.

3. *Kneading*, i. e. a muscle is lifted and kneaded between the finger and thumb or between the fingers and the palm, or between the two thumbs, or the whole limb may be squeezed and rolled between the two hands. The effect of kneading is evidently deeper than that of friction, and the mechanical effect is greater.

4. *Tapotement*, or percussion. The part is repeatedly and rapidly struck with the hands of the manipulator used alternately. The whole of the palmar surface of the hand may be used (clapping), or the tips of the fingers (punctation), or the ulnar border of the hand (hacking), or the clenched fist (beating). The effect is to produce a local hyperæmia which may extend deeply.

5. *Vibrations* are carried out by oscillatory pressure with the tips of the fingers over the line of a nerve trunk, or by similar movements of the whole hand, the palm being applied to the surface of the body; vibrations with the palm are chiefly used over the abdominal organs. The whole of a limb, *e. g.* the arm, may also be shaken by grasping the hand, fully extending the arm and shaking rapidly.

Vibratory movements can be readily and efficiently applied by means of an electrically or hand-driven vibrating machine. Such a machine should be capable of vibrating at the rate of 2000 or more vibrations per minute, and should be capable of adjustment so that the range and frequency of the vibrations can be altered. Many of the local circulatory and mechanical effects of massage can be obtained with such a machine.

These methods of massage produce their effects, then, chiefly upon the skin, subcutaneous tissues, muscles and other soft parts and upon the nerves. To a less extent the abdominal organs can be reached. In general the effects are to improve the local circulation, both mechanically by assisting the venous and lymphatic flow, and also by producing a local hyperæmia. The depth to which this circulatory effect is produced depends upon the method used. There is also a mechanical effect in deeper movements by which indurated tissues may be softened and adhesions stretched. Certain movements have, moreover, a local analgesic or soothing effect, whilst others, such as deep frictions, beating and vibrations if applied over nerves have a stimulating effect upon them.

Movement in treatment means the carrying out of normal movements of the joints within their normal range. They are of two main varieties, Passive and Active.

Passive Movements are carried out by the manipulator without any assistance from the muscles of the patient. They may be gentle, *i. e.* carried out within the limits of the movement permitted without resistance, or forcible, *i. e.* aiming at increasing the range of movement where this is not complete.

Active Movements may be simple (free movements) or they may be resisted by machinery or by pressure applied by the manipulator.

Resisted movements may be described as concentric or eccentric. Concentric are those in which the muscle or muscles concerned shorten, acting against an external resistance, *e. g.* flexion of the elbow by the biceps and brachialis anterior in opposition to a resisting force. Eccentric movements are those in which the muscles are stretched by an external force which they resist, *e. g.*, extension of the elbow by an external force, the biceps and brachialis anterior resisting and being gradually stretched. Eccentric movements may be very useful in the treatment of paralysed muscles which have not sufficient residual power to perform their normal work. For example, if

the biceps has not sufficient power to flex the elbow, it may still be exercised by making it resist whilst the forearm is supported and gradually extended.

Active movements may be supplemented by a passive stretching movement carried out by the manipulator at the end. Thus active flexion of the elbow may be carried out to the limit of possibility, and the elbow then forcibly flexed a little further.

All varieties of movements—active, passive, resisted or combined—can be carried out by the aid of machinery of the Zander or Pendel type, but practically everything that can be done by machinery can be done by hand and done with greater accuracy and delicacy. The chief use of such machinery is to reduce the labour of manipulation.

Movements may be carried out with several different objects. (1) To preserve the function of the joint. (2) To improve the function of a damaged joint by restoring its full range of movement. (3) To preserve or improve the strength or activity of a muscle or muscles. (4) For their effect upon the general health, *e. g.* to reduce obesity, to improve the circulation or for their mental effect.

Evidently the variety of movement used and the method of applying it must depend on the object to be attained. Whereas active joint movements will suffice to maintain the function of a joint, passive movements are necessary to increase it. Active movements may have several different effects upon the muscles according to the method of application. They may simply increase the strength of the muscles, or they may improve the rate of contraction, making the movements more rapid, or they may improve the control of the muscles, making the movements more accurate. It will be noticed that active movements have thus an important effect upon the nervous mechanism of the movement, and their use in this direction is often more important than their use to strengthen the muscles.

In order that active movements may be made to subserve their different purposes, certain points on their application require careful attention. In the first place, if the control of muscular movement is to improve it is important that the initial position from which the movement is to be carried out shall be correctly assumed, at first as the result of careful directions, later spontaneously. Further, the movement must be carried out accurately and in proper time. If muscles are to be strengthened to a greater or less extent, the work they are made to do in the course of a movement must be regulated, resistance, manual or mechanical, may be applied, or some method of altering the length of the lever moved by the muscle by shifting the centre of gravity of the part moved may be utilised. For example, a good exercise for the iliopsoas, rectus abdominis and other abdominal muscles is performed by lying on the back with the feet fixed and slowly raising the trunk to the upright position. The strength of this may be varied by altering the position of the arms. It is easiest with the arms by the side, more difficult with the arms at a right angle and the hands behind the neck (neck-rest position) and most difficult with the arms stretched upward above the head.

The difficulty of an exercise may be varied in another and quite different way. The initial position from which the movement is carried out may be altered, with considerable consequent variation in the difficulty of the exercise. There are five primary positions: standing, lying, sitting, kneeling, and hanging, as well as a number of positions derived from these. A given exercise may be very much easier in the sitting than in the standing position, because the support given to the pelvis in sitting relieves the patient of the necessity of maintaining his balance. Similarly, a trunk movement is easier in the stride position in which the feet are separated than in the ordinary standing position in which the heels are together and the feet turned out, and the exercise is made more difficult still by assuming the close standing position in which the heels and toes are in contact. In this example the exercise is made progressively more difficult by decreasing the base of support. Exercises in a position in which the base is small are called balance exercises, and are specially useful in improving the nervous control of the muscles involved.

By combining movements they may be made much more difficult. For example, a trunk and an arm movement may be carried out simultaneously, or a trunk movement may be carried out until a new position, requiring a certain muscular and nervous control to maintain it, is attained, and arm movements may be carried out in this position. The extra difficulty in these cases falls chiefly on the nervous mechanism of control, so that combined and complicated movements are of use chiefly in progressive training in co-ordination.

These principles, here very briefly stated, form the basis of methods of treatment by movements and by exercises.

Movements or exercises applied to a particular part of the body are used to obtain some particular local effect, *e. g.* to strengthen particular muscles or increase the mobility of joints. Their object will regulate their nature and mode of application. They are usually combined with massage, which should always be applied at the end of the treatment, and in the case of stiff joints at the beginning also.

In using more general exercises the effects of the treatment on the respiration, circulation and general health must be borne in mind. The table of exercises should as a rule begin and finish with breathing exercises, easier movements should be followed by more difficult, resisted movements involving considerable strain should be followed by free movements involving more rapid action. At the end of the table, massage should be carried out over the muscles which have been principally exercised, and the patient should then take half an hour's rest. The termination of all tables of exercises by breathing exercises and by massage greatly lessens the after fatigue, the breathing exercises improving the general, the massage the local, circulation.

General massage and abdominal massage require special mention. In general massage the patient lies on his back completely undressed but well covered with bed-clothes. Massage is then begun upon one lower limb working from the foot up to the groin, each joint as it is reached being put through active and passive movements. The other lower limb is treated next, then each arm in turn, working from the hand upwards. The neck and pectoral regions are next massaged, then the abdomen, and finally the back and buttocks. General massage should occupy from half an hour to an hour, the duration and the severity of the treatment being regulated in accordance with the condition of the patient. Each part as it is massaged must be carefully covered. General massage is used for many different purposes. Its effect may be soothing or stimulating, according to the methods employed. Frequently its use is as a substitute for ordinary forms of exercise which the patient is unable to take. The operator should always be conversant with the disease from which the patient is suffering and with the object of the massage.

Abdominal massage may also have several different objects. It may be used chiefly for its effects upon the abdominal muscles, or for its effect upon the intestinal tone and movements. These two constitute its most important objects, but it is also advocated for its effect upon the portal circulation, and for its effect upon the liver, kidneys, spleen and uterus.

The most useful abdominal movements are: deep circular kneading over the central part of the abdomen (the region occupied by the small intestine), deep kneading along the line of the large intestine from the right iliac fossa upwards to the right flexure of the colon, across the line of the transverse colon and down the left side into the pelvis. These two have a direct stimulating effect upon the intestinal walls and also a mechanical effect upon any collections of fæces. Frictions and stroking over the abdominal wall have also a stimulating effect upon the intestine as well as upon the abdominal muscles. Further, exercises for the abdominal muscles are useful in such a condition as chronic constipation.

Abdominal massage and exercises are also useful after abdominal operations, in patients who are confined to their beds, and in the treatment of obesity.

Treatment of the stomach, liver, spleen and kidneys are prescribed by some. It cannot be said that these have much to commend them, and if carried out roughly and unskilfully they might be dangerous.

Massage of the uterus, through the abdominal wall, to assist involution, is practised regularly by certain obstetricians. It is begun the day after the confinement and continued until the patient leaves her bed. Exercises for the abdominal muscles are useful in the later stages of the puerperium.

Massage and Exercises in Special Diseases

General Diseases.—General massage is of great use in the treatment of deficient nutrition in delicate people, specially those of sedentary habits, in anæmia of all sorts, in nervous diseases, in hysteria, during convalescence from acute or chronic disease, or after operations and in obesity. The massage must be graduated according to the condition of the patient and the stage of treatment. In obesity vigorous massage, especially vigorous kneading, is advisable.

Nervous Diseases.—In addition to massage which has an obvious use in maintaining the nutrition of the muscles, exercises are of special service in nervous diseases.

In hysteria exercises improving co-ordination and balance, and involving a certain amount of concentration, have great mental effect, and also assist in the treatment of local manifestations. Many hysterical deformities can be completely cured by carefully designed exercises. General massage is an essential part of the Weir Mitchell treatment.

In diseases of the lower motor neurone, such as poliomyelitis, massage of the affected muscles should be carried out from the first. Passive movements are necessary to prevent contractures and active movements to assist the recovery of paralysed muscles by functional use. Eccentric movement may be specially useful when the muscles are left too weak to carry out their normal concentric action. The same applies to neuritis and to injuries of the nerves. In neuritis and in nerves involved in cicatricial tissue vibrations (manual or, better, instrumental) over the nerve trunk are much used. Fine vibrations gently administered have a definite soothing effect and diminish the pain in neuritis. Stronger vibrations are said to

stimulate the nerve trunk; they almost certainly produce a hyperæmia in the nerve and assist in diminishing the fibrosis of a nerve in old-standing neuritis or in scarring after an injury. Massage and vibratory massage thus help to relieve the pain in old-standing neuritis or in painful scars and to improve the conductivity of the affected nerve. In progressive diseases of the muscles or lower motor neurones, such as progressive muscular atrophy and the various myopathies, massage has, of course, only a palliative effect. It will not stay the disease, but by maintaining the nutrition and functional use of the muscles it will diminish the rate of apparent advance.

In paralysis due to a lesion of the upper motor neurone massage and movement have to be applied upon a rather different principle. The diseases included in this group are for the most part of a fixed type and not progressive; as examples, infantile spastic paraplegia, diplegia and hemiplegia, and hemiplegia resulting from cerebral embolism, hæmorrhage or thrombosis, may be taken. The effect of these lesions upon the neuro-muscular system may be divided into loss of muscular power, loss of control (inco-ordination), spasticity, athetosis, stiffness of joints and trophic changes. The last two are more marked in the late-acquired than in the infantile cases. Stiffness of the joints and coldness of the extremity affected are attacked by the ordinary methods of massage, including the use of vibrations. Loss of power is similarly treated. But spasm and athetosis are not likely to be improved and may even be increased by massage vigorously applied. In cases in which these symptoms are marked only the gentlest frictions should as a rule be employed; these may diminish the spasm. Spastic muscles must be gently stretched by the hand; daily stretching does some good, but in cases with much spasm it is necessary to keep the muscles stretched continuously by means of a splint or to attempt to diminish the spasm by surgical means.

The most important part of the treatment of paralysis of the spastic type consists in the training of the muscles by exercises in order to re-educate control and co-ordination. The object is to put the joints systematically through their normal active movements, and it is essential to observe the position of neighbouring joints at the same time. For example, in spastic paraplegia flexion and extension of the foot may be voluntarily possible and may be carried out with fair accuracy if the knee-joint is flexed, but may be very difficult if the knee is kept extended. The muscles must be educated until all foot movements can be carried out voluntarily and accurately in all positions of the knee.

The training of a patient with spastic paraplegia in walking after the spasm has been relieved by such operations as tenotomy, nerve section, or posterior root section is a long and laborious business and may occupy two years or more. It involves education first in all joint movements taken separately and individually, then in standing with the knees and hips fully extended, first upon both feet, later upon each foot separately, then finally in the movements of stepping and walking.

In diseases such as tabes, in which the muscular sense is lost, re-education by exercises is again the underlying principle in treatment. Here the senses of sight and touch must be made to replace the sense of position which should be inherent in the muscles. The exercises most used are those devised by Fraenkel. In addition to simple voluntary movement of the joints, special exercises for the proper co-ordination of the legs and arms must be carried out. Lying down, the feet are moved at the word of command and placed in one of a number of slots in a notched board, walking is practised upon a floor space which is marked out with footprints into which the feet must be accurately placed. Then the patient is shown how to rise from a chair, first placing his feet back beneath the centre of gravity of his body, a movement instinctive in the normal person, but one which has to be learnt again when the sense of muscular position is lost. Finally, such movements as turning have to be practised. The arms must be exercised by seizing one of a number of fixed pegs, by fitting pegs into holes, by picking up and arranging small articles and similar exercises in co-ordination, the exercises being graduated so as to be increasingly difficult. Very great improvement in co-ordination may be thus secured in the majority of cases.

Diseases of the Thoracic Organs.—Improvement in the possible and in the habitual range of the respiratory movements is one of the most evidently advantageous results of well-designed physical exercises. Such breathing exercises, besides being useful in all sorts of general conditions of debility, etc., should be carried out as a routine in the treatment of deficient chest expansion co-existing with nasal obstruction, after operations for adenoids, in the subjects of frequent nasal and pharyngeal catarrh, and in those with kyphosis and flat chest. In chronic bronchitis and in asthma massage of the chest and abdomen is often advocated, and may in some cases be beneficial. It must, however, be carried out with careful supervision, and expiratory movements rather than deep inspirations should be practised.

After pleurisy, empyema or other conditions in which the chest expansion is asymmetrical, breathing exercises are important and, in fact,

almost essential. Unilateral movements in which the expansion of the sound side are hindered may be used.

In heart disease massage and graduated exercises are often useful; they should invariably be carried out under close medical supervision, as it is very easy to do more harm than good. It is impossible here to do more than briefly state the principles involved. General massage is sometimes useful by dilating arterioles and assisting the venous flow; it will often relieve an embarrassed heart, but it is easily seen that such a peripheral dilatation of the arterioles may in some cases do positive harm. Breathing exercises are again of service in assisting the circulation mechanically. Graduated exercises combined with the natural effervescent baths form the basis of the Nauheim treatment. The baths have a general stimulating effect upon the skin, which relieves the heart probably by producing dilatation of the peripheral arterioles. The graduated exercises are designed to increase the work of the heart slowly, and so to bring about a sufficient compensatory hypertrophy. Local massage over the heart is advocated in some systems of massage in the hope that it will stimulate the heart directly. It is very little used in this country, and in fact such direct stimulation of the heart, if it is possible, does not appear to be by any means necessarily advantageous.

Diseases and Injuries of the Joints.—In maintaining or restoring the function of a joint after injury or disease treatment by massage and movement finds one of its chief uses. In considering the principles upon which they must be applied it is necessary to differentiate clearly between massage and movement. Often both are advisable, but almost equally often it is necessary to employ massage whilst keeping the affected joint at rest. The simplest method of differentiating between lesions of joints that require rest and those that require movement is to act upon the old advice, "Rest all inflamed structures," bearing in mind that in modern pathology the reaction of the tissues to an aseptic injury is not inflammation, and that inflammation must also be differentiated from the subsequent period of organisation of the inflammatory products. In sprains and allied injuries the first object is to get rid of any effusion; massage with the assistance of a firm (compression) bandage will in most cases rapidly effect this. The second object is to restore the mobility of the joint; this is effected by movements. Throughout the treatment the nutrition of the muscles is maintained by massage, and as soon as they can be performed by active movements. The most difficult question to decide is the time at which movements should be commenced. It may be said at once that the presence of an effusion is no contra-indication, nor is the occurrence of a moderate amount of pain on movement. The only reason for withholding movements in the treatment of a sprain is the existence of a known injury to an important ligament, so that there is a risk of preventing its union and so leaving a weakened joint. This in most joints is an exceptional occurrence, and when it has occurred it contra-indicates movements in certain directions only, for with due care other movements can be carried out from the first. As soon as there is no risk of displacement of the joint, active movements and functional use of the joint are advisable, the joint being supported by strapping if necessary. Sprains thus treated by early movement recover rapidly. Excessive resting of a joint after injury is a prolific cause of periarticular adhesions, which in subsequent movements of the joint are pulled upon and stretched, leading to attacks of synovitis.

In acute or subacute arthritis due to some form of bacterial infection, massage may, if thought advisable, be carried out from the first, or at least as soon as the more acute symptoms have subsided and it becomes clear that the inflammation is about to subside without suppuration. But during this stage it is better not to attempt movements of the joint, in fact, fixation upon a splint is often desirable. In such a form of arthritis as that due to the gonococcus the best indication for beginning movements is the subsidence of the pain. It may be laid down as an axiom that attempts to move the joint during the early painful stage, by increasing the inflammation, will hinder the return of movement in the joint and may even lessen the movement that is subsequently restored. So that, as a rule, massage of the joint and of the muscles should be performed early, movements as soon as they are not accompanied by much pain, and the latter should always stop short of producing severe pain. If it is found that no progress is being made, it is better to examine the joint under an anæsthetic, some of the adhesions can thus be broken down, and at the same time information may be obtained as to the amount of recovery likely eventually to result. In tuberculous arthritis it is hardly necessary to say recovery of movement must be spontaneous, it is never allowable to attempt to obtain it manually, although massage of the muscles is a perfectly correct treatment.

In osteo-arthritis and in old-standing rheumatoid arthritis comparatively little benefit is to be expected from treatment by massage and movement, unless there has been a neglect of all endeavour to retain mobility in the joint during the earlier stages. In more recent rheumatoid arthritis, however, very great benefit may result

from appropriate treatment, but it is necessary to bear in mind what has already been said about attempting to force movement in an inflamed and painful joint. First, the more acute progress of the disease must be arrested; active and passive movement may then be used with benefit.

Fractures.—Great misconception exists as to the uses and limitations of massage and movements in the treatment of fractures. These methods can only be accessory to the other methods of treatment, but they are accessories that cannot in the interests of the patient be ignored. In order that the limitations of their employment may be understood, it is necessary to allude briefly to the reduction of displacement and to the splinting of fractures. Displacement of the fragments in a fracture may be caused by the force which produced the fracture, or it may be the result of the pull of muscles, or of the weight of the limb. If the first named be the sole cause, as it is, for example, in Colles's fracture, there is no tendency to the recurrence of the displacement when this is once reduced; if the second or third causes are concerned there may be a tendency to such recurrent displacement, and this may have to be guarded against by a splint or by an extension. The chief limitation to the employment of massage and movement in the treatment of fractures is that necessitated by this tendency to recurrent displacement. This must be analysed in each case. In Colles's fracture there is no tendency to recurrence, massage may be employed from the first, and the splint may be removed in order that it may be carried out. In Pott's fracture the splint may be removed for massage at the end of a week; in practically any fracture, including that of the shaft of the femur, the splint may be removed for a massage at the end of three weeks. The object of the early massage is to assist absorption of effusion, and it is obviously desirable to begin this portion of the treatment as early as possible—that is to say, as soon as the part can be got at. The question of movement is less simple. It is necessary to insist that by movement we mean normal joint movement, and not movement of the fractured ends of the bone upon each other. Such normal joint movements may with advantage be carried out as soon as there is no risk of producing displacement. They must be gentle from the first, never pushed to the extent of causing much pain, and any movement which might displace the fragments must be avoided; for example, in a Pott's fracture, flexion extension and inversion of the foot may be commenced early, eversion of the foot should be left until after about three weeks. It is specially necessary that all massage and movement in the treatment of a fracture should be gentle. Massage aids the formation of callus; if carried on vigorously, particularly if accompanied by vigorous attempts to force movement, the callus may be produced in an amount that becomes embarrassing. The production of excessive new bone around the elbow after a fracture of the lower end of the humerus is undoubtedly partly, if not entirely, due to too-vigorous treatment by massage and movement, and the complete cessation of the treatment will usually suffice for its cure. In the method of treatment of fractures by massage identified with the name of Lucas Championnière, the necessity for gentle treatment is specially insisted upon. This French school also use repeated centripetal stroking of a limb as an analgesic; it is stated that by this means in the course of a few minutes the area of a fracture may be rendered practically anæsthetic, so that muscular spasm is relaxed, and a recent fracture if not impacted may be reduced without pain.

Spinal Curvatures.—The treatment of spinal curvatures, kyphosis, lordosis and scoliosis, by exercises has been elaborated into a system, or rather perhaps systems, of considerable complication. It is only possible here to allude briefly to the principles of treatment and to its limitations. All spinal curvatures are capable of classification into postural curves, in which the spine is anatomically normal and can be restored by the patient's own muscular effort to a good shape, and structural curves, in which there is a structural deformity of the spine, usually in the vertebræ, but sometimes in the muscles, so that the patient cannot by his own muscular effort attain a proper posture. In the first class of case the treatment is purely a muscular problem; a properly designed system of exercises is capable of effecting a cure. In the second class of case exercises are only subsidiary to other forms of treatment. By themselves they may prevent any progress of the deformity, but they cannot completely cure it, the most that they can do is to enable the patient to maintain such a posture as will hide the deformity. This is often all that can be promised by any method of treatment.

In drawing up a table of exercises for a patient suffering from a spinal curvature all the points already alluded to must be borne in mind. The table, with massage at the end, will last, as a rule, from forty minutes to an hour. It should begin with breathing exercises and a few plane arm movements, include a considerable variety of exercises, which must be changed from time to time so that they do not become monotonous, and should end with more breathing exercises and massage of the back muscles. The principles that have to be borne in mind, are—

1. That the first essential is to train the

patient to maintain her best posture, at first as the result of directions, later of her own accord. So that the first essential is that the instructor should see that the initial position from which exercises are carried out is correct.

2. That control of the muscles must be obtained. At first the patient finds it difficult to carry out the movements accurately at the word of command and requires assistance. She gradually, however, attains more complete command over her own muscles.

3. The strengthening of the muscles in general or of particular groups is the third requisite. This is, however, less important than the improvement of muscular control.

4. In structural curves correction of the more fixed part of the curve by manipulation with the hands or with straps, or by stretching over the boom, is desirable.

The carrying out of exercises for the treatment of a spinal curvature is a matter of considerable difficulty, and the instructor must be carefully chosen. Exercises to improve posture and control of muscles will not effect their object if they are carried out in a slovenly way however well they may be designed. Exercises which are intended to strengthen muscles are even more difficult. If badly designed and carried out they may easily make a curve worse. It is, in fact, a common occurrence to find that a patient by vigorous exercises has been made considerably more deformed, or at least that the curve has been made more fixed.

R. C. E.

TREATMENT BY HYPNOTISM, SUGGESTION AND PSYCHO-ANALYSIS

The two chief methods of treatment in use at the present time which depend for their results on their influence on the mind of the patient are suggestion, with or without hypnosis, and psycho-analysis. The rôle of the two methods is entirely different, and while many of the neuroses may be benefited by either used separately, a number can be best alleviated by a combination of the two.

I.—The method of **Suggestion during Hypnosis** is that mainly used in this country.

The chief characteristic of the hypnotic state is increased suggestibility; and this is seen in every stage from the lightest hypnosis to the deepest sleep. But increased suggestibility is not the only phenomenon characteristic of the state. An obvious loss of spontaneity is usually to be observed, especially in the later stages, the subject remaining motionless except when carrying out a suggestion. Marked loss of memory distinguishes a subject aroused from the deepest stage, he being quite unable to recall the events of his hypnotic sleep.

The subject is not only more susceptible to suggestion in hypnosis, but is able to realise the idea suggested with an intensity quite impossible in waking life. Thus, if a lady in the normal state is told that her dress is on fire, she will accept the suggestion to act accordingly; but, when she sees that the suggestion is false, she will no longer act on it. If, however, she be hypnotised, she will both act in accordance with the idea, and will really see the smoke and flame, and so become subject to an hallucination. Many of the phenomena induced by suggestion occur spontaneously in other abnormal conditions. Such are the anæsthesias and paralyses of the hysteric, and the stigmata of certain religious devotees, etc.

The different stages of hypnotism can be distinguished by the particular groups of suggestions which can be enforced in each.

(*a*) **Stages.**—In the first stage, one of the phenomena most easily induced is inability to open the eyes. Heidenhain pointed this out many years ago, and stated that in many subjects it was the only sign that could be elicited —and I fully concur with him. It appears that in the *first stage* all one can do is to inhibit those actions which are usually carried out reflexly, though by voluntary muscles. Such are the movements of the eyelids, swallowing, breathing and micturition. Sneezing, which is a purely reflex act, though carried out by voluntary muscles, can be inhibited whether the subject be hypnotised or not. Thus practically no one, when told that, when he takes a pinch of snuff or pepper, he will be unable to sneeze, can do so.

In the *second stage*, ordinary voluntary movements can also be inhibited. For example, the patient is unable to loosen an object when told he cannot, or drop anything which he holds in his hand, though it is easier to prevent him from dropping a heavy than a light object. He cannot pass a line drawn on the floor; he cannot get up, and even cannot speak if silence be suggested. It is during this stage that so-called contracture or muscular rigidity can first be induced. The limbs are stroked, and the suggestion is made that they are stiffening. The subject is quite unable to relax his muscles until that suggestion is removed. Possibly the initial inability to open the eyes is due to contracture of the orbicularis oculi muscle. He cannot perform actions, sometimes because he feels under a strong disinclination to try, sometimes because he cannot make up his mind to do so. More commonly, however, he can and does try; and, though he contracts the appropriate muscles, he is obliged to contract their opponents so strongly that he cannot achieve the forbidden action. Thus, if he is

told he cannot loosen the operator's hand, when he tries to do so, he will grasp it more firmly instead.

In the *third stage* imperative suggestions begin to take effect, and the subject can be compelled to begin and to carry out an action. He can be made to laugh, to get up, or in fact execute any desired movement.

In the *fourth stage* he can usually be induced to forget any selected fact. Thus he cannot recollect his own name if told he cannot. Local analgesia can also often be induced, and semi-hallucination also. For example, a paper-knife held in the hand may be made to seem so heavy that it drags the holder to the ground, and so hot that he must throw it down.

In the *fifth stage* visual and auditory hallucinations can be induced; but the memory is intact, or nearly so, on the awakening.

In the *sixth stage* all the phenomena of the previous stages can be evoked; but the memory of the events occurring during this stage is abolished on awakening, though it may be revived during subsequent deep hypnotic states. The condition in this stage is often termed somnambulism.

It is in this stage that what are known as post-hypnotic suggestions can be most effectually made, and from a therapeutic point of view they are of great importance. If during somnambulism a patient is told that at some time after he awakens he will do a certain action, he does it as suggested. But he is utterly unaware on awakening that any such suggestion has been made, and, as a rule, when he carries it out, believes the action to be done of his own free will.

It is interesting to notice that by persistently assuring the patient that he can remember what happened during his sleep, he can often be persuaded to recall the events partially or completely. It was this phenomenon that first turned Freud's attention to the possibility of making patients recall long-forgotten episodes, which led to the discovery of Psycho-analysis.

It will be seen from the above brief account that the popular idea that the subject becomes "unconscious" during hypnosis is entirely false. At all stages, even the deepest, he is acutely conscious. The notion has probably arisen from the amnesia which follows the sixth stage. It appears to be a peculiarly mischievous idea in practice, many patients insisting that they have not been hypnotised because they were fully conscious the whole time.

The results of hypnosis vary greatly with different individuals. Some show the phenomena at the very earliest stages, and while many show the phenomena of the first three or four stages, only about twenty per cent. pass into the sixth. I may here note that a few subjects show the phenomena of the second stage before those of the first; but these are quite exceptional.

(*b*) **Theories.**—There is, so far, no completely satisfactory explanation of the phenomena of hypnosis. On the physiological side, the theory of dissociation, which has been ably advanced by Dr. McDougall (*Brain*, July 1908) seems the best proposed, although purely speculative. It assumes variation of resistance in the different neurones during hypnosis which cause alterations in the direction and amount of the flow of neurokyme or nerve energy.

On the psychological side various theories have been advanced, largely founded on the changes of memory—or rather the loss of memory—on awakening from somnambulism, its recovery during subsequent hypnoses, and also on the curious phenomena of motor and sensory automatisms. Most of them suppose that a disintegration of consciousness takes place, the total consciousness being partially or completely split into two—the waking consciousness and the subconsciousness, the subconsciousness alone being affected by suggestion. It is, however, doubtful whether the term subconsciousness is not really a misnomer, and whether "the unconscious" does not come nearer to reality. Munsterberg considers that the "subconsciousness" has no existence, and that the phenomena attributed to its activity are simply automatic processes, analogous to the automatic playing of a practised musician, in which consciousness has no real part. It is a conception not unlike that of Carpenter's "unconscious cerebration."

But as a working hypothesis the fundamental idea of a split-off consciousness is extremely useful, even though it may not be absolutely accurate. However, the problem is still unsolved. Hypnosis, then, may be regarded as a condition of artificially induced suggestibility. Sidis has laid down the following conditions as necessary for the induction of the state—

1. Fixation of attention.
2. Monotony.
3. Limitation of voluntary movements.
4. Limitation of the field of consciousness.
5. Inhibition (*i. e.* the inhibition of all extraneous ideas).

Of these the essential condition is the fourth—limitation of the field of consciousness; the rest are merely useful in securing it.

One may suppose that concentration somehow causes the consciousness to split into two paths. This is seen in a slight degree in the phenomenon known as passive attention. A man engrossed in conversation, walking in a crowded street, does not collide with his fellow passengers, but avoids them. Yet this avoidance may

be almost entirely unconscious. His "passive attention" has been brought into action by his mental absorption, forming a kind of protective mechanism, and we may suppose that the action is in some degree subconscious. At any rate there is no doubt that mental concentration does result in increased suggestibility.

(*c*) **Methods.**—Numberless methods may be used based on this principle. Personally I generally use one which is designed to prevent, as far as possible, any conscious resistance on the part of the subject. The patient is told that he really hypnotises himself, and that all any one else can do is to help him in the process. He is impressed with the idea that the essential point is the concentration of his attention. I tell him to fix his attention as much as he can on some small object held about eight or ten inches from and slightly above his eyes. He is told to blink as much as he likes, and to let his eyes get as heavy as ever they will, not to rouse himself on any account, but to sit motionless, with all muscles as relaxed as possible. After a few seconds the forehead is quietly stroked, and suggestions are commenced, such as, "Your eyes are feeling heavy already. They are beginning to close," etc. In a very short time, as a rule after less than two minutes, the eyes close. I now lay my hand firmly on the patient's forehead and say, "Your eyes are fast—you cannot open them, you may try as much as you like"; and it is quite rare for a patient to do so.

As might be expected, patients may at first find difficulty in concentrating their attention and preventing the entrance of extraneous ideas; and, until they can, each trial for hypnosis is a failure. Hence, if hypnosis cannot be induced the first time, they must be trained in concentration. Success can almost always be assured after a few trials if this discipline is carried out.

Once the first stage is reached, even if no deeper hypnosis is possible, therapeutic suggestions may be commenced.

This initial phase being induced, attempts may be made to deepen the hypnosis, both by suggesting the phenomena of the stages in their proper order, and by the reiterated suggestion of sleep. Even though no sleep be induced, this suggestion tends to deepen the condition.

Increased suggestibility for therapeutic purposes may be induced by other methods than hypnosis.

(*d*) **Hypnoidal State, etc.**—In the hypnoidal state, first described by Sidis, the patient becomes sufficiently suggestible for therapeutic purposes, though perhaps not so much as in hypnosis. The hypnoidal state is intermediate between the state of waking and that of normal sleep: it is unfortunately, but naturally, often very transient. It can be readily induced by any means which will cause sound sleep. The patient may lie with his eyes closed in a darkened room, and some monotonous sound such as the beating of a metronome, the ticking of a watch, or the sound of running water, will usually suffice to bring it about. The breathing becomes slightly irregular, and the patient resists and resents any attempt to move his limbs; I have also noticed slight spasmodic movements of the limbs.

Therapeutic suggestions given in this state are often highly successful. Bramwell's method of giving suggestions in a monotonous tone of voice, while the patient rests with closed eyes, and attends, not to him, but to some restful train of thought, depends probably for its success on the occurrence of the hypnoidal state. Altogether, this mode of treatment is useful for patients who decline to try hypnotism, or who are insusceptible to it, for it consists simply in making suggestions in the normal waking state.

It may be pointed out that the mechanism called into play is entirely different to that acting in hypnosis. The suggestion merely persuades the patient to look at his complaint from a rational point of view, so that by his own reassurance he may break away from his morbid condition. Hypnotic suggestion, on the other hand, makes no appeal to his rational self, but only to his subconsciousness. In treating by the hypnoidal method, the aim is to get the patient to understand his illness and its causes—a rather difficult matter if the physician himself happens to be at a loss as to what they are.

It is also necessary that the patient should be intelligent enough to understand the purpose of the treatment. In addition, the physician must be a man of unlimited patience and great powers of persuasion. The treatment is, therefore, only useful in a limited number of cases, but in these the results appear to have been excellent.

II.—Psycho-Analysis

The method of treatment elaborated by Prof. Freud of Vienna is applicable to many cases of psychoneurosis. But it must be clearly understood that its scope is distinctly limited. It is of no use in early childhood or old age; it requires from the sufferer great patience, an intelligence at least equal to the average, and, what is rare in the English at any rate, the power of casting away all reserve whatever, while from the physician it demands at least an equal patience and rare gifts of psychological penetration.

According to Freud's theory the psycho-

neuroses have their origin in ideas combined with emotion, forming what are called complexes, which complexes exist, not in the normal consciousness, but in what Freud terms the "unconscious." These systems of ideas acting apart from, and often in antagonism to, the waking consciousness, induce the symptoms of the various neuroses, *e. g.* phobias, imperative ideas, paralyses, etc. They are the result of unfulfilled "desires" existing in the unconscious. But if the complex causing the symptoms be slowly illuminated, and the patient made to realise and recollect its origin, the symptoms vanish, sometimes at once, more often gradually. The process of unearthing the complex is called Psycho-analysis.

As before stated, it is possible to get hypnotic subjects to recall the events occurring during somnambulism by repeatedly insisting that they *can* remember them. By a similar process Freud found that he could sometimes get patients to recognise what the complex was that caused their symptoms; and since then other methods have been devised for the same object, especially the method of "free association," and the interpretation of the patient's dreams.

Under "free association" the patient lies at rest, fixes his attention on some fact connected with his illness, and observes the ideas and images which present themselves to his mind. He must simply observe, not criticise in any way, lest the ideas be influenced by his mental attitude, though naturally it takes a little practice before he can do that. Each image as it arises he watches intently, and describes minutely to the physician, who firmly insists that ideas of some kind must rise up to his vigilant and waiting consciousness.

His dreams also he must try to recollect and describe with equal minuteness. The images of dreams are always symbolic in adults, and Freud, in his work on *The Interpretation of Dreams*, gives a number of symbols, the meaning of which his vast experience has enabled him to determine.

Other methods there are, notably that of Jung, in which a list of words is read to the patient, he uttering the first word that occurs to him as each is read. Partly by the reaction time, by the response-words given by the patient and in about ten other ways, hints are obtained which may serve as beginnings for fresh trains of analysis.

As a rule, the patient must be seen for about an hour at a time. By constant questioning, and insistence that the subject *can* remember, with the aid of the interpretation of his dreams, and the images and ideas aroused by free mental association, the complex is gradually reached, and eventually completely unmasked.

In every case, according to Freud, there is a sexual basis for psychoneurosis, though many disagree with him. He goes so far as to state that with a normal sexual life psychoneurosis never occurs, so that the aim is really to determine the actual sexual trauma which is at the base of the symptoms. The process is a very long one, lasting months and sometimes years.

It appears to me that it is not suitable for trial in many cases, as no one would wish to suggest unpleasant and revolting sexual ideas to those in whom they do not exist. But when there is a strong probability that some sexual shock lies at the root of the mischief, there cannot be the same objection. Even then, however, it would seem unlikely that it would be possible to break down the reserve of the average Englishman, and an intentional refusal to give the details, often repulsive details, is an absolute bar to success in a task already rendered difficult by the *unconscious* resistance of the patient as he or she becomes dimly aware of the nature of the neurotic symptoms.

III.—Maladies Amenable to Suggestion

In treating patients by suggestion, it is found that, although the results may be more rapidly obtained in the deep states, the very lightest hypnosis is often sufficient.

Suggestion may be successfully used in treating other than purely mental disorders; constipation, dysmenorrhœa, metrorrhagia, amenorrhœa, hyperhydrosis and other functional complaints have been successfully treated. Forel gives the following list of complaints to which it is especially applicable—

Spontaneous somnambulism, pains of all descriptions, insomnia, functional paralysis and contractures, organic paralyses and contractures (as palliative means), chlorosis, disturbances of menstruation (metrorrhagia and amenorrhœa), loss of appetite and all nervous digestive disturbances, constipation and diarrhœa (provided that the latter does not depend on catarrh or fermentation), gastric and intestinal dyspepsia (including pseudo-dilatation), psychical impotence, nocturnal emission, masturbation, perverted sexual appetite and the like; alcoholism and morphinism (only by the suggestion of total abstinence), chronic muscular and arthritic pains, lumbago, the so-called neurasthenic disturbances, stammering, nervous disturbances of vision, blepharospasm, pavor nocturnus of children, sickness and sea-sickness, and the vomiting of pregnancy, enuresis nocturna, chorea, nervous attacks of coughing, hysterical attacks and bad habits of all kinds. All hypochondriacal paræsthesias, irritable weakness, conceptions of impulse and the like are more difficult to treat.

It must not be supposed that the above list is necessarily exhaustive. Some of the complaints given, too, will often yield to analysis, or analysis combined with suggestion, but may be quite unamenable to suggestion alone. Such are functional paralysis and neurasthenic and hysterical disturbances.

But many are eminently suited to hypnotic treatment alone. Of these I may mention a few of the commoner and more important.

(*a*) **Insomnia.**—Whilst hypnotism often cures cases of chronic insomnia, it is generally quite useless in an emergency case, where it is important to induce sleep immediately, unless the patient happens to have been hypnotised on some previous occasion. In chronic cases the results are often good. The patient must, however, usually submit to a regular course of treatment, though occasionally I have found a single hypnosis sufficient to cure permanently a disease of long standing, in one instance the case being of seven years' duration.

(*b*) With **Alcoholism** in most of its forms, suggestion is eminently successful.

The three chief forms of this disease are: true dipsomania—a comparatively rare disease—pseudo-dipsomania, and chronic alcoholism.

In *true dipsomania* the attacks of craving are independent of the taking of alcohol, and occur even during periods of total abstinence. As a rule the attacks are heralded by premonitory symptoms which last a week or more, and the ensuing debauch of alcohol endures a few days, after which the frenzy ceases, often leaving the patient very ill for a little. In course of time the next attack occurs, exactly in the same way. Very few of these patients can drink in moderation between the attacks: some, however, can, being apparently perfectly normal until the attacks happen. I do not believe that hypnotism has the slightest effect on these cases. The attacks can, however, be satisfactorily treated on the lines laid down by Dr. Francis Hare.

In *pseudo-dipsomania*, the patient remains free from any attack for an indefinite time, the collapse arriving only if he takes alcohol. Usually a single glass will ensure the occurrence of a drinking bout. In the majority of these cases, alcohol produces depression after the first stimulating effects have gone. The time in which depression develops varies enormously. With one patient it occurred always within twenty minutes of taking the first glass. In another it did not come on for nearly thirty hours. The craving in these cases consists in a desire to escape from the feelings of misery; and alcohol immediately relieves the patient, only to plunge him again into the same condition later. Some have told me that the reason they did not stop was that they dared not. Many dislike the taste of alcohol extremely during an attack; but that is no obstacle to their taking it. As a rule, after a few days—a week or more—the patient suddenly ceases to drink, often because his stomach is too much upset for him to go on. The amount these people will consume is astounding. Three bottles of whisky a day is not unknown, and one patient whom I saw took no fewer than four.

In *chronic alcoholism* the patient drinks in excess quite regularly; I should say the average amount taken by such a case is one to one and a half bottles of whisky a day. Any sudden diminution after a long period of chronic alcoholism is liable to lead in a few hours to delirium tremens. I am convinced by experience of the correctness of Dr. Hare's contention that sudden withdrawal is exceedingly dangerous and liable to cause most alarming sequels. It is, I think, certain that in the cases on which the opposite view is founded the habit had been of short duration, in dealing with which total withdrawal is generally perfectly safe.

In treating alcoholism by suggestion the first essential is absolute abstinence from all intoxicants. This may be insisted upon immediately in the attack of the pseudo-dipsomaniac. With the chronic alcoholic matters must be contrived very slowly and cautiously. After the alcohol has been stopped, for which purpose the patient is much better left in bed, suggestive treatment may be begun. In my experience all alcoholics, except those whose condition is due to head injury, are readily hypnotised.

The suggestion in all cases must centre on making the patient a total abstainer, and strengthening his will power, special emphasis being laid on the absolute necessity of never again taking a first glass. Suggestion of increased self-control and terror of alcohol are useful; the latter I have found in several cases acting so as to prevent the fatal taking of the first glass in a casual way.

There are two other forms of dipsomania which I think deserve special mention, viz.: *menstruation dipsomania*, occurring in women only at the periods; *dipsomania due to insomnia*.

The first is often associated with irregular menstruation, and depression at the periods, the patient feeling that she must have something to "pick her up." It is possible to render menstruation regular in some of these cases, and to limit its duration exactly, and also largely to combat the depression. These cases may do exceedingly well: out of four cases of the kind only one relapsed, the rest having been free from any attacks since treatment, two for five years and one for three and a half years.

The insomnia cases are specially interesting,

the cure of the insomnia resulting at once in the cure of the dipsomania, some of these patients being the only ones I have met who can afterwards drink in moderation, becoming apparently absolutely normal.

Authorities differ as to the time during which an alcoholic patient should be under treatment. Personally I generally see my patients every day for eight days, twice during the ensuing week, once the week after, and then, if possible, regularly at long intervals of a month or six weeks for an indefinite period.

It must always be borne in mind that all these cases are liable to relapse, for there is no possible cure for the original nerve condition. And it is here that the chief advantage of the treatment comes in. A few days' treatment after a relapse will usually suffice to keep the patient safe for a still longer period; and though in some cases relapses may occur again and again, the patient has long periods between during which he can enjoy his life, instead of being almost constantly under the influence of the drug.

(*c*) **Morphinomania.**—As with alcohol, the first thing is to stop the taking of the drug. This must in all cases be done gradually if the habit has persisted for long. It is only the last grain or so which it is so difficult to give up; and the time required for this renunciation may be very prolonged. Thus, in one case of twenty years' standing, it took six weeks to leave off the last grain, the dose being diminished by one forty-eighth of a grain each day. But after the drug is given up there is for a long time great risk of the patient's beginning to take it again; and though suggestion answers in many of these cases, if they are not treated for some two, or even three, months, they usually relapse.

With regard to cocaine, I fear that treatment is practically useless. A confirmed case is hopeless.

(*d*) **Bad Sexual Habits.**—With young children, under twelve, the result of a single suggestion is, as a rule, immediate and complete, the habit ceasing at once. In adults the cure takes much longer. It is important to insist in these cases that the only possible way a patient can fight this particular vice is to govern his thoughts, and never allow himself to dwell even for a few seconds on sexual matters. One can give him power by suggestion to turn his thoughts away at once, and the cessation of the habit follows spontaneously.

(*e*) **Impotence** in the male, if of psychical origin, can frequently be cured, even after a duration of years. The idea causing the impotence must be sought for and counteracted, and for this purpose psycho-analysis is often essential. However, even if the idea be unknown, mere suggestion may be sufficient.

(*f*) **Absence of sexual desire,** and primary vaginismus in the female may be cured. The latter especially is, as a rule, quite amenable to suggestion.

(*g*) **Dysmenorrhœa,** especially of the so-called spasmodic type, I have seen vanish at once after many years' duration.

Prolonged and irregular menstruation also can often be regulated to the exact day of onset and cessation, especially if somnambulism can be induced.

(*h*) **Hysteria.**—These cases differ enormously in the degree to which they respond to suggestion. In some the symptoms vanish at once; in others not at all. These cases are really best treated by some process of psycho-analysis, either by itself or in combination with suggestion. In neurasthenia, analysis will frequently relieve the symptoms when other methods fail.

In hysteria there is often a considerable difficulty in inducing hypnosis of even the slightest degree. Hysterical subjects are often extremely self-suggestive—a condition highly unfavourable to hypnosis. It is in these cases especially that analysis has proved so useful. But the method is so tedious, treatment lasting for months and even years, that it is for most of us, except in quite rare cases, almost impossible, and in the view of many it is more than doubtful whether its advantages are not outweighed by the detailed sexual analysis which it involves. But it is possible by a partial analysis in many cases to gain sufficient knowledge of the ideas causing the symptoms without going deeply into sexual details.

Thus, in one patient who was unable to go out alone, because she was seized with terror if she did so, the unconscious idea causing the terror was that she would go mad, and that the people in the street would seize her and hurry her off to an asylum. Suggestion removed the idea at once; and the fear vanished. But according to Freud there would be found a sexual basis for this idea, if analysis were completed. There may have been, but I never attempted to discover it, and it appears to be unnecessary to do so, in some cases, at all events.

Cases of obsession, melancholia and sometimes imperative ideas (though often these are very stubborn) may be benefited, as well as the various phobias.

(*i*) **Complaints not Definitely Mental in their Nature.**—Of these *Constipation* is the most typical, and can often be permanently cured. Cases of lifelong constipation may yield to suggestion; I have seen one of fifty-three years' standing completely and lastingly relieved. The suggestion should be made that the bowels will act at a specified hour. Even if a daily evacuation cannot be obtained, it is often

possible to obtain one every second or third day.

Menstruation, as mentioned previously, can often be regulated exactly; and the pain of spasmodic dysmenorrhœa obviated.

Chorea will sometimes vanish almost immediately.

Some cases of *Eczema*, presumably of nervous origin, are reported to have been completely and rapidly cured.

Nocturnal Enuresis often yields; but is very uncertain, for many cases fail to improve. It occurs often in such deep sleep that the patient is apparently beyond the range of suggestion.

With *Stammering* in young persons of fifteen or under the results are very good, and success is often obtained in adults. I have found self-suggestion very useful with these patients.

Attention must be paid to the cause of stammering, *e. g.* wrong breathing, etc., if it can be discovered. Some cases occur after whooping cough, and these I have failed entirely to improve.

Forel states that the results in *Chlorosis* are extremely good. The hypnotic sleep without suggestion is said to be beneficial.

In *Asthma* the results during an attack are almost magical, and I have seen a fair number of cases in whom self-suggestion can be most effectively used. The results are not, as a rule, permanent; but the attacks can usually be shortened.

Sickness and sea-sickness are generally easily preventable, and the vomiting of pregnancy is said to be relieved. Suggestion has, of course, been used as an anæsthetic; but since the introduction of physical anæsthetics it has naturally fallen into disuse. As a rule the patient must have had some previous hypnotic training. The anæsthetic value of suggestion is still useful for the removal of pain, such as that of headache or neuralgia, and is, I think, specially suitable for confinements.

H. E. W.

TREATMENT OF TUMOURS BY DIATHERMY CAUTERY

The apparatus required for Diathermy consists of a motor which produces a high-frequency current of great power and two electrodes, a large one which is wrapped in wet towels and laid on the patient's chest or abdomen, and a smaller one which has a metal end which can be applied to the tumour. The passage of the strong current through the small electrode, or cautery, produces intense heat which rapidly destroys the tissues. On the other hand, very little heat is produced in the region of the larger electrode because of its greater size.

By diathermy it is possible to destroy any amount of tissue, but care should be observed that the sloughs produced are not too large, otherwise there may be septic absorption or bleeding if a large artery lies in the immediate neighbourhood of the wound.

Treatment is carried out in the following manner: A general anæsthetic is required. The growth must be sponged until the surface is quite dry. The small electrode or needle must be plunged into the growth so that all the metal is covered. The current is then turned on and in five to ten seconds the tissues around the metal are completely destroyed. As soon as the parts become white, or when bubbles appear on the surface of the tumour, the current must be switched off. By a series of similar punctures every part of the growth can be attacked. The operation can be completed in about five minutes. Even with vascular tumours bleeding is very slight, but the surface of the growth requires frequent sponging to keep it dry.

Diathermy for Malignant Growths.—The author has treated cases of inoperable carcinoma with this method during the last five years. The growths have involved the palate, tonsil, base of tongue and pharynx, and were associated with urgent dysphagia, blood-spitting and constant expectoration; many of them were considered too advanced for operations with the knife. There has been very little pain even after extensive destruction of tissue, and the patients could swallow well in twenty-four to forty-eight hours. It is remarkable that the surrounding tissues do not become much inflamed, and there appears to be no tendency to œdema such as occurs with milder forms of burning. The sloughs produced by diathermy separate in five to ten days, leaving a healthy wound without discharge. In many instances the ulcer disappears and the parts are covered with soft mucous membranes. When the whole of the growth has been destroyed there is no tendency to scar formation, as frequently occurs after other operations. There has been no shock, and the patients have only been confined to bed for twenty-four hours. Secondary hæmorrhage has not occurred and there have been no other complications except slight burning in the region of the larger electrode. In most cases more than one operation was found to be necessary.

All the patients were definitely improved by the treatment. The best result was obtained in an old man with a growth on the front of his tonsil and adherent to the upper and lower jaws. Seven applications were made, and he lived for two years after the first application.

In most of the cases improvement was only temporary, but the patients were relieved of severe pain and were able to swallow more

easily. In one case of carcinoma of the cheek it was found possible to excise the growth some weeks after the application of diathermy. In two cases the primary ulcer was destroyed by burning and cervical glands were removed by a second operation. In another instance radium treatment was also given and the patient was definitely improved.

There appears to be no difficulty in destroying the superficial parts of these diseases and the throat is more comfortable afterwards. There is no evidence to show that the cancer cells are more easy to kill than normal tissues. It is possible that there is less tendency to recurrence than after a cutting operation, because the blood- and lymph-vessels are sealed by burning. In some of the cases where growth remained, it became atrophic in character. Diathermy is also valuable for the treatment of early growths, but it is yet too early to say whether the method will give as good results as the knife in this or other parts of the body. The obvious advantages are the rapidity of the operation and the possibility of destroying a dangerous growth without the loss of a single drop of blood.

Diathermy for Nævi.—Vascular cavernous nævi of the tongue, pharynx, nose and in rare instances of skin, can be safely treated by diathermy. The heat developed by the instrument is so intense that there is no tendency to bleeding. Secondary hæmorrhage does not occur even when a part only of the nævus has been treated.

Diathermy may also be used in rare instances for other conditions, such as lupus of the mucous membranes of the upper air passages, for destruction of enlarged or septic tonsils, or for removal of innocent neoplasms.

W. D. H.

SPECIFIC THERAPY

The object of specific therapy is to promote the patient's recovery from a given infection by raising his resistance to the particular pathogenic micro-organism by which he is being attacked. It has been shown that recovery from a bacterial infection depends in no small degree upon the ability of the patient to put forth and maintain a sufficient supply of specific antibodies. The aim of specific therapy, therefore, is to increase the patient's fund of specific antibody. For this purpose three practical methods are at present available, viz: (1) Vaccines; (2) immune serums; (3) sensitised vaccines.

Vaccines.—A vaccine consists of a suspension of a pathogenic micro-organism either attenuated or killed. In certain special instances, *e.g.* tuberculin and mallein, the bacterial bodies are disintegrated and a solution of their contents is used. In either case the active principle of the preparation is the endotoxin of the bacterial bodies. The first step in the preparation of a vaccine is to obtain a pure culture of the micro-organism. In the majority of instances, *e.g.* in case of staphylococcus, streptococcus, pneumococcus, gonococcus, M. catarrhalis, meningococcus, B. coli, B. typhosus, B. pyocyaneus, etc., a young culture on agar is suitable. It is advisable to use a strain recently isolated from the body, and when possible the patient's own micro-organism is preferable; in which case the vaccine is said to be autogenous. As it is impossible to make an autogenous vaccine in every case, stock vaccines are made in most hospital laboratories by mixing several strains of the same micro-organism and keeping the mixture in stock for use as required. Having obtained a suspension in saline of a young culture of the organism, the next step is to standardise the vaccine by determining the number of bacterial bodies in a given volume. This may be effected by one of several methods. In the procedure devised by Wright a measured volume of the suspension is mixed with a volume of blood and after thorough admixture film preparations are made, stained, and the number of bacteria and red corpuscles respectively counted in a series of fields; the number of red corpuscles in a cubic millimetre of blood being known, it is easy to find the number of bacteria in the saline suspension by this method.

A second method of standardising a vaccine is to mix a volume of it with an equal volume of a dilution of some stain such as methylene blue, and then to count the number of bacterial bodies that deposit from the mixture over the squares in a Thoma-Zeiss counting chamber. Other methods are also available. It is usual to label vaccines by the number of bacterial bodies that they contain per cubic centimetre.

Mode of Sterilising the Vaccine.—Vaccines are killed either by heat, in which case a temperature at or about 60° C. is generally used, or by an antiseptic such as phenol, lysol or ether, or by autolysis. In the last case all that is necessary is to put a suspension of the organism in saline into the incubator at 37° C., and to leave it there overnight. Provided the emulsion is not too strong, a subculture on the following day will show that the micro-organism is dead.

Keeping Capacity.—Vaccines should be kept in a cool place and in the dark. It is advisable to seal them off from the air. Though they may be active after being kept for a year or more, it is generally advisable to use them within a few months of their preparation.

Mode of Administration.—Vaccines are given in nearly all cases subcutaneously. The site at

which they are injected is immaterial, the loose tissue on the extensor aspect of the forearm, or the arm, or the flank are equally suitable.

Dosage.—This varies according to the condition of the patient and the kind of organism in use. The rule is to begin with a small dose and gradually to increase it unless the patient gets a "reaction." A reaction may be either local or general, or in the diseased area. In the first case there is some redness and œdema at the site of inoculation. A general reaction is characterised by malaise and a rise of temperature; in severe cases there may be a rigor. When there is a reaction in the diseased area there is some slight aggravation of the local symptoms. The reaction is produced by too large a dose of the vaccine, and it may come on at any period from half an hour up to forty-eight hours after the injection. Although there is as a rule marked improvement after it has passed off, the reaction is better avoided, and this can be effected by beginning with a low dose and by not raising it too rapidly. As a rule much smaller doses of vaccine should be used in acute cases than in chronic. In most cases 1–5 millions is a suitable dose to begin with, but in cases of boils or acne in which Staphylococcus vaccine is used, it is safe in most cases to begin with an initial dose of 50–100 millions. In an ordinary case doses of vaccine may be given once a week.

Modus Operandi and Choice of Cases for Treatment.—The object in giving a vaccine is to promote the formation of antibodies by the body cells. Thus, in the case of a person suffering from boils on the back of the neck, the introduction of a suitable dose of staphylococcus vaccine under the skin of the forearm appears to cause first a small fall in the amount of circulating antibody (negative phase)—a fall, however, which is quickly followed by a much greater rise in the antibody production, and corresponding with the latter there is an improvement in the clinical condition of the patient. In bad cases of boils or of furunculosis, however, it is necessary to give at least six injections at weekly intervals before the skin is cleared up: the result of this procedure, if successful, being a cumulation of the positive phase of antibody formation.

As a rule chronic cases are more suitable for treatment by ordinary vaccines than acute ones, but perhaps the best results are seen in some obstinate acute cases in which the temperature keeps up without any obvious reason. In vaccinating an acute case with an ordinary vaccine it is necessary to proceed with much caution owing to the serious effect of any diminution in the specific resistance of the patient. Among the acute cases that have been treated by vaccines are acute infections by the streptococcus, pneumococcus and B. coli—cases, that is, of cellulitis, erysipelas, puerperal sepsis, angina Ludovici, pneumonia, bronchopneumonia, colitis, etc. Among chronic cases treated by vaccine are prolonged suppuration of any kind, such as cystitis, colitis, empyema, and arthritis of gonococcal origin or due to some other suppurative focus such as pyorrhœa or a vaginal discharge. Some degree of success has also been obtained in a proportion of cases of persistent catarrh of the upper respiratory passages, and in cases of pruritus. Increase in the specific resistance effected by vaccination is often of only temporary duration, especially in those cases of long-standing localised infection where the general resistance of the patient has been undermined. It is important to bear in mind that the action of a vaccine is not to remove the cause of the patient's illness, but to stimulate his specific resistance to the fullest degree possible in the circumstances. Hence, in cases such as those of general septicæmia with meningitis, in bad cases of puerperal sepsis where the endometrium is found at the post-mortem to be sloughing, and in cases of ulcerative endocarditis, in all of which conditions the specific defence of the organism is already fully stimulated by the living bacteria at work in the patient's system, it is hardly a matter of surprise that the injection of ordinary vaccine is without effect.

Immune Serums.—If the object of giving a vaccine is to stimulate the patient to produce his own antibody, the second method of specific therapy supplies him with antibody already made by an animal such as the horse in response to vaccination. The best known of the immune sera is that which contains diphtheria antitoxin. The use of this serum has been one of the great successes of specific therapeutics. Potent though this specific remedy be, it is all important to give antitoxin early in the attack, and to give it in a large enough dose, *e. g.* at least 4000 units. Tetanus antitoxin has been much less successful. One reason for this is that by the time the patient develops symptoms of tetanus the specific conjunction of the toxin with his central nervous system has been already effected. Hence, in such cases the intraspinal or intracerebral injection of the serum is indicated. Another practical reason of the failure of tetanus antitoxin is the fact that these patients almost always have a mixed infection; the tetanus bacillus being associated with anærobic gas-forming bacilli, or B. coli, or streptococci, or perhaps with all three micro-organisms. Of the other immune sera the most notable perhaps is antimeningococcus serum. This is administered intraspinally in the following way. Lumbar puncture having been performed, 10 to 30 c.c. of the

cerebro-spinal fluid are withdrawn, and then, without removing the trocar, a similar amount of the immune serum is injected. The patient's head should be lowered after the injection in order to facilitate the circulation of the serum through his cerebro-spinal system. Of other serums antistreptococcus serum has proved useful in some acute cases.

In certain circumstances there is a source of danger in the use of immune serum from anaphylactic shock. This phenomenon of anaphylaxis is as follows—

If an animal is given a dose of the serum of another species—be that dose even a minute one—and an interval of from ten to twelve days or longer is allowed to elapse before another dose is administered, the animal on the second injection may undergo severe constitutional disturbance with collapse that may be fatal. If, however, the second dose of serum is given before the tenth day, there is no anaphylactic shock. Besredka, who has made a special study of the prevention of anaphylactic shock, or as it is termed "antianaphylaxis," has made the valuable discovery that anaphylactic shock is prevented if at the time of the second injection the susceptible animal is anæsthetised with ether, or if it is under the influence of a large dose of alcohol given either by mouth or by the rectum. Furthermore, he finds that if a small dose of the serum is given per rectum ten hours before, or subcutaneously five hours before, or intravenously five minutes before the second injection, it produces a condition of antianaphylaxis in an otherwise susceptible animal.

Sensitised Vaccines.—A third method of specific therapy which is now available consists of sensitised vaccines. This method was introduced by Besredka in 1902 and has certain advantages that deserve special mention. A sensitised vaccine is a vaccine which has been combined with the specific antibodies present in the serum of an animal immunised against the organism of which it is a suspension.

In making a sensitised vaccine all that is necessary is to leave the suspension of bacterial bodies in contact with immune serum at the room temperature for twelve hours. At the end of this time the bacteria of the vaccine have combined with their specific antibodies in the immune serum, and are agglutinated at the bottom of the tube. The supernatant serum is removed, and the deposit of bacteria is suspended in saline and then centrifugalised. The saline is removed, and the process of washing repeated. In this way all traces of serum can be removed, all chances of anaphylaxis obviated, and a vaccine obtained that is combined with its specific antibodies, or in other words is sensitised.

Besredka prefers to use living sensitised vaccines, but though this is probably the best method of immunising at present available, most people prefer to take no risk, and to kill the bacteria by adding 0·5 per cent. phenol to the saline with which the vaccine is washed after it has been sensitised.

During the ten years that have elapsed since the introduction of sensitised vaccines a large amount of experimental evidence has been accumulating with regard to their value, and it has been demonstrated that sensitisation of a vaccine has the following advantages—

1. The toxicity of the vaccine is enormously reduced.

2. The onset of the resulting immunity is accelerated.

3. It produces no negative phase or "reaction." It will be realised that these advantages make sensitised vaccines especially suitable for the treatment of acute cases, and they can be recommended for the treatment of acute infections by the Streptococcus pyogenes and by B. coli. Their clinical value in cases of pneumococcus infection is less established at present owing to the difficulty of getting an immune serum that thoroughly sensitises all strains of that organism. Similarly, in infections by the staphylococcus and by the gonococcus the difficulty is to get a serum that adequately sensitises a vaccine of these organisms. This difficulty, however, is unlikely to be a permanent one, and even a partially sensitised vaccine appears to have the conspicuous advantage over an unsensitised vaccine that it is less liable to produce a diminution of the patient's resistance.

Owing to the sensitisation it is possible to give sensitised vaccine in very much larger doses than the unsensitised.

In a series of cases of acute infection by Streptococcus pyogenes the writer obtained a marked improvement in a large proportion of the cases by giving doses 100, 500 and 1000 millions of the sensitised vaccine on three days in succession according to the intensive method of immunising devised by Fornet and Müller.

Such dosage and such a method of immunising would have been unsafe with ordinary vaccine. It was of interest to find that in two of these cases successfully treated with sensitised vaccine, ordinary vaccine and also antistreptococcus serum had been tried without avail. One of these cases, in fact, when the autogenous vaccine of streptococcus was pushed to 7 millions, developed a reaction with rigor and became distinctly worse; yet when this same patient was started with 25 millions of the same streptococcus after sensitisation, and the dose doubled every day for six days, he gave no reaction, but showed considerable improve-

ment; and after two more courses of sensitised vaccine he gradually recovered.

Sensitised vaccines would appear to be specially applicable for preventing infection in the case of epidemics, since they do not reduce the patient's resistance, and the resulting immunity has been shown by animal experiments to have already begun within twenty-four hours of injection.

They would also seem to have a field of usefulness in prophylaxis by raising the specific resistance of patients to sepsis before operation on the alimentary, urinogenital or respiratory tracts. Further they might be used medically in the same way in order to raise the resistance of patients to secondary infections which may be likely to occur at a later stage of their disease. M. H. G.

TREATMENT BY THE FINSEN LIGHT AND ULTRA-VIOLET RAYS

To Finsen, of Copenhagen, we owe the application of concentrated light to the treatment of diseases of the skin. The apparatus required is expensive, and the technique demands the constant attention of skilled assistants, factors which render its use in private practice impossible.

The essential features of the apparatus are—

1. A powerful source of light. In southern countries sunlight may possibly be used, but in Great Britain and in northern latitudes generally, a powerful electric arc is used. In the original apparatus of Finsen, an arc lamp giving a light equivalent to 30,000 candles is used, and this requires a special transformer or dynamo. The Finsen-Reyn modification can, however, be worked from the ordinary electric lighting mains (with a *continuous* current) and it gives equally good results.

2. A telescopic tube, provided with a series of rock-crystal lenses, by means of which the rays from the arc are first rendered parallel and then brought to a focus, this focus being the area under treatment. The telescope contains a column of distilled water, kept constantly cool by a water-jacket, to remove the heat rays given off by the electric arc.

3. A compressor applied to the skin at the focus of the rays. This compressor consists of a metal ring fitted with two plates of rock-crystal, the upper plate being parallel with the lower end of the telescope, while the lower plate, usually convex, is pressed firmly on the area under treatment. Through the compressor, a constant circulation of cold water is maintained to prevent the skin being burned by the concentrated rays emerging from the telescope.

The modus operandi is as follows—

The patient, suffering, we will suppose, from lupus of the face, is placed comfortably on a couch. The area to be treated, having been marked by a blue pencil, is brought exactly into the focus of the rays and then the compressor is applied with sufficient pressure to blanch the part. It is essential that the area under treatment be rendered anæmic, otherwise the actinic rays would not penetrate the skin. Having thus brought the spot to be treated in the focus of the rays, the patient is maintained in this position with the compressor held by a nurse (or in certain suitable cases fixed by a special apparatus) for one hour. The area treated is as large as a shilling. About six hours after the treatment the part becomes inflamed and a blister forms. It is essential that a blister should be produced; if vesication does not occur there has been some error in the technique, probably inadequate pressure, improper focussing, or dirty water in the telescope. The blister is dressed with a mild antiseptic ointment twice a day until healed. In cases of lupus this process is repeated until every part of the affected area is devoid of the nodules characteristic of the disease. Great care is taken to prevent irritation of the eyes. When the light has to be applied near them, the eyelids are closed and covered with layers of brown or red paper, which cut out the actinic radiations.

The condition in which this treatment excels is lupus vulgaris. It is especially indicated in lupus of the face, where the cosmetic result is of the highest importance. The scar is soft and supple, and, in many cases it is impossible, without the closest examination, to detect the site of the previous disease. The process is tedious, it is true, and demands considerable perseverance on the part of the patient and his attendant, but the results are worth the time and trouble expended to produce them. I have many patients, formerly entirely debarred from obtaining a livelihood by the disfigurement of their disease, who have been constantly employed at remunerative wages for years. As regards the permanence of the results, I have had many patients free from any sign of relapse for ten years.

A certain proportion of the patients are only partially benefited, and in these cases the disease has been widely spread, or there has been extensive disease of the nasal and buccal cavities. In a very small proportion the disease spreads too rapidly for the treatment to cope with its ravages.

When the lupus is of the ulcerative form, preliminary treatment of the pyogenic inflammation accompanying the tuberculous process is required, fomentation and the application of antiseptic ointments being necessary. In some

cases a preliminary treatment of ulcerative surfaces by X-rays has proved of great assistance.

Wherever necessary, the general condition of the patient receives the usual tonic treatment and extra nourishment.

Mercury Vapour Lamps.—A useful form of apparatus for producing a smart superficial inflammatory reaction by the actinic rays of light is the Mercury Vapour Quartz Lamp of Kromayer. This consists of a U-shaped quartz tube containing mercury vapour connected with an electric continuous current and enclosed in an envelope of metal, faced with a quartz plate. On the current being passed the tube is tilted so that the mercury flows from pole to pole and the vapour then becomes incandescent. The rays given off by the incandescent mercury vapour are intensely actinic. The heat rays are eliminated by a chamber between the source of light and the part to be treated, through which cold water is passed. An application of ten minutes is sufficient to cause a smart reaction with blistering, but the penetration is not so good as in the concentrated rays of Finsen's apparatus. Kromayer's lamp may be used for superficial forms of lupus. It is of more value in the treatment of some chronic forms of eczema, lichen, and in the flat warts of children.

Other Applications of Actinic Light.—Actinic light may be applied also to stimulate the growth of hair in certain forms of alopecia. Here I find Kromayer's apparatus is of service. A blue screen is used and the light applied for ten to twenty minutes to produce a definite inflammatory reaction. This need not go beyond an erythema, and can be repeated at intervals.

The treatment of vascular naevi by the Finsen light is very tedious, and other measures are preferable.

Lupus erythematosus of the chronic type occasionally reacts well to treatment by the actinic rays of light, but in practice I find that such cases are more amenable to carbon dioxide snow or to plasters, salicylic acid, etc.

J. H. S.

THE METHODS OF TREATMENT BY EXTREME COLD

The agents used in the treatment of cutaneous affections by extreme cold are: (1) liquid air, (2) solid carbon dioxide.

1. **Liquid Air** (temperature 182° C.) is procurable in special bottles made on the principle of the Thermos flask. The bottle is sent out in a box packed with straw to prevent jarring. Not less than one litre can be obtained, and this quantity generally costs fifteen shillings. It is, therefore, economical to have several cases to treat at one time, for the liquid air speedily disappears by evaporation.

To apply the liquid air sponge-holders holding lint or gauze swabs and a porcelain capsule are necessary. An assistant pours into the capsule the liquid air, which at once "boils." The swab held in the sponge-holder is dipped into the liquid and is immediately applied to the surface to be treated. I prefer to run over the whole area first rapidly and lightly, as this cools the surface and makes the following application more satisfactory. The swab is again dipped in the liquid and pressed firmly on the spot under treatment. This at once becomes white and looks as if a strong escharotic had been applied. The process is repeated until the whole area has been covered. In a few minutes, the white, hard-frozen patch thaws and resumes its normal appearance. When the face is being treated, care must be taken that the liquid air does not run into the ear or mouth, and the eyes must be carefully covered. Naturally, the eyelids must be avoided in cases of nævi.

After a varying time, from an hour to several hours, a blister forms containing clear serum. This is dressed as if it were a superficial burn, and the dressing may have to be continued for a week to a fortnight. It is exceptional to get any ulceration, unless the part has been scratched. In young children it may, therefore, be necessary to restrain the hands. When the parts are soundly healed, the treatment may be repeated.

The actual application is not very painful, but the thawing process causes intense pain, which, however, soon passes off.

2. **Solid Carbon Dioxide.**—The carbon dioxide or carbonic acid "snow" treatment was introduced by Pusey. It has the advantage of being much cheaper than liquid air, and the gas is easily obtained. When carbonic acid is released from a cylinder through a narrow nozzle into a bag, its escape causes a portion to be deposited as masses of thick flakes exactly resembling snow. The temperature of the solid is − 79° C. Gas cylinders containing seven to fourteen pounds are obtainable from the wholesale druggists.

A simple method of making the solid dioxide is to have a nozzle to fit the mouth of the cylinder, and to apply round it a washleather bag (a sponge-bag will do). The key of the cylinder is turned and the gas is allowed to rush out, at first in two or three short jets, and then for a longer period, according to the amount required. By touch, one is able to tell by the crackling sensation whether there is "snow" in the bag. The key is then turned off and the bag removed to a table or slab. Moulds made of metal or vulcanite of various sizes are now used to mould the snow into a solid stick. The

mould is provided with a rammer by which the snow is compressed. In treating a small area, care should be taken that the end of the stick is not larger than the spot to which it is to be applied. If necessary, the stick, which cuts like chalk, may be pared down or shaped with a penknife. In treating larger areas, square applicators are best, as it is easier to fit the squares together, or the method to be described presently may be used.

Various forms of apparatus for the making and moulding of the snow are on the market, and convenient portable cylinders with the necessary moulds can be obtained from the surgical instrument makers.

The stick or pencil of solid carbon dioxide, held in a piece of lint, is pressed firmly on the affected skin for from ten to forty seconds, or more, according to the effect required.

The result is a white, hard depression in the skin, which in five minutes fills up and resumes its normal colour. An inflammatory reaction with blistering, follows, and the inflamed, blistered surface is dressed with a simple antiseptic ointment. The treatment may be repeated when the reaction has passed.

There is comparatively little pain, except during the thawing process. If the application be too prolonged, especially if accompanied by strong pressure, sloughing may occur. Each application costs only a few pence.

Another method of applying carbon dioxide was introduced by Dr. W. K. Sibley. It consists in dissolving the snow prepared as above described in ether or acetone. The snow is dropped into a capsule containing the ether or acetone, and at once a "boiling" occurs. When a sufficiency of the snow has been dissolved, a jelly-like substance forms. This is applied to the affected surface on a camel hair brush, and the same whitening and shrinking of the skin occurs, followed by the return to the normal colour. This method is especially useful when treating areas of irregular surface or irregular outline, when it is difficult to get an even result with the solid stick. In using this solution, care must also be taken that the liquid does not run into the ear or the mouth. The after treatment is the same. In my experience, this method is attended by more pain than the application of the solid pencil.

Selection of Cases

Treatment by extreme cold is of value in some forms of vascular and pigmented nævi (moles), lupus erythematosus, superficial rodent ulcers, senile keratomata and warts. Success has been claimed in certain cases of lupus vulgaris, but the scope of the treatment in this form of skin disease is very limited. I have seen some very ugly scars on the face caused by prolonged endeavours to get rid of small patches of common lupus by the solid stick. At the bottom of the deep cicatricial pits characteristic nodules of lupus were plainly visible, although much healthy tissue had been destroyed.

It remains now to indicate briefly the special conditions in which the freezing treatment is indicated and some points of importance in dealing with them.

(*a*) **Vascular Nævi.**—The port-wine stain (simple angioma) can be treated by liquid air, and admirable results may be obtained if the nævus is not too deep. In all cases the surface becomes paler, but the treatment may have to be repeated again and again. Painting with carbon dioxide snow in ether is also suitable. The solid stick is not so useful, even when a square applicator is used, as it is almost impossible to get a smooth result, owing to the areas treated at each application being small and difficult to fit together; a mottled surface is a common result. I do not think that the results of either of these measures are so good as those obtained by radium, but the radium treatment of port-wine stains is a very tedious and costly business.

Nævus Cavernosus.—The raspberry mark of limited area, so commonly seen in infants, is best treated by the solid stick exactly moulded to fit the area. Moderate pressure is applied for about thirty seconds or more. The resulting scar is, as a rule, admirable. Care must be taken not to press too deeply or too long, or sloughing will occur, and this leaves an ugly scar. In the treatment of nævi of this variety on the face, I advise a first short application to avoid a disfiguring cicatrix. In many cases, one application is sufficient, but the treatment can be repeated after three or four weeks if necessary. If the snow pencil goes over the edge of the nævus, a white halo round the cicatrix is almost certain to be left and this makes the scar very conspicuous. Deep-seated cavernous nævi of the skin or subcutaneous tissue are best treated by electrolysis or by radium.

Stellate or *Spider Nævi*, the minute, rounded red spots with radiating vessels, common on the faces of children, are not suitable for the snow treatment. They are best dealt with by electrolysis or puncture with the fine-pointed cautery.

(*b*) **Pigmented Nævi** (pigmented moles).—Pigmented moles of small dimensions can be treated successfully by the carbon dioxide pencil, but the applications have usually to be repeated several times. A deep reaction is necessary because the nævus extends deeply. The hair follicles can be destroyed by this method if the subject be young. In older cases, electrolysis of the hairs may be required subsequently.

When the pigmented mole is of large dimensions, *e. g.* covering one half of the face or a large area of the body, the snow treatment is unsuitable. When the face is affected, the case should be referred to a surgeon skilled in skin grafting. The cosmetic result of such operations is not very satisfactory, and the child's parents must be allowed their option between an extensive mole, the nature of which every one knows, and a graft with its abnormal colour, which may excite even more comment than the birthmark.

(*c*) **Lupus Erythematosus.**—In the chronic variety of this disease, characterised by symmetrical, well-defined scaly patches on the cheeks, nose, etc., the application of the carbon dioxide pencil for ten to twenty seconds, or painting with the ethereal solution, often gives very satisfactory results. The reaction causes the formation of crusts, and, on their removal, a smooth cicatrix. Internal treatment by quinine, salicin, etc., must be carried on at the same time. Acute forms of lupus erythematosus should not be treated in this way. The result of such stimulation will very likely be an extension of the area of the disease.

(*d*) **Rodent Ulcer.**—Small superficial rodent ulcers can be removed by the application of the carbon dioxide pencil. I advise an application of at least forty seconds, with firm pressure. The reaction which results causes the parts treated to become inflamed and a crust forms, which should be allowed to separate spontaneously. A dressing of boric ointment may be applied. The application of the pencil may have to be repeated. The scar left is not so good as that following treatment by radium or curetting with subsequent application of the X-rays. I have several times been asked to treat by radium, or by curettage and the X-rays, cases of rodent ulcer which the snow treatment has failed to cure. In the deeper varieties of this disease, the carbon dioxide treatment is not suitable.

(*e*) **Senile Keratomata** are the flat yellowish-brown warty growths seen on the face and hands and elsewhere in elderly subjects. They may become malignant, and therefore require early treatment. They are, as a rule, readily removed by the solid stick applied as for the common wart.

(*f*) **Warts.**—The freezing treatment applied to common warts so frequently seen on the hands and fingers of children gives most satisfactory results. A pencil is shaped exactly to the size of the wart and is pressed firmly upon it for forty seconds. In large, hard warts, a minute's treatment may be given with advantage. The wart shrinks, but unless it is soft there is no depression left when the stick is removed. The wart soon resumes its original size and very often there is no inflammatory reaction, but the excrescence drops off in a few days, leaving a smooth, red surface. In some cases a second application is required.

The soft filiform warts of the scalp may also be removed by the application of the solid pencil. Occasionally, I have seen some septic inflammation follow from scratching the sores left by the reaction, and in one case this caused an acute inflammatory swelling of the warts treated, necessitating prolonged fomentation. The ultimate result, however, was perfect.

J. H. S.

RADIUM TREATMENT

The element Radium was discovered by Madame Curie in combination as a salt, but has since been separated in the pure state.

It is classified as a metal of the alkaline group and is very similar to barium. Its atomic weight is 226·5 times that of hydrogen; it is therefore one of the heaviest metals.

The bromide is the most active salt. It occurs in the form of small white crystals which are very soluble in water. It is hygroscopic, and if exposed to the air will gradually absorb sufficient moisture to become liquefied.

The chloride has the same properties, but is not as powerfully radio-active.

The sulphate and carbonate are white powders insoluble in water; they are also less radio-active than the bromide.

The term "radio-active" is now generally applied to a class of substances such as uranium, thorium, radium and their compounds, which possess the property of spontaneously emitting radiations capable of passing through plates of metal and other substances opaque to ordinary light.

The most remarkable property of the radio-active bodies is their power of radiating energy and heat spontaneously and continuously, at a constant rate, without, so far as is known, the action upon them of any external exciting cause. They also act on photographic plates and discharge electrified bodies.

The radiations from radium are very intense. The radium emanations are analogous to those of uranium and consist of three types of rays—

(*a*) Alpha (easily absorbed).
(*b*) Beta (penetrating).
(*c*) Gamma (very penetrating).

The *Alpha Rays* are readily stopped by a thin sheet of paper. They are used therapeutically in the form of the emanation either by inhalation alone or combined with oxygen, or by injection after absorption in water, oil or other media. A further field for their use is to deposit the emanation upon suitable substances and apply

direct to the tissues requiring treatment. Water takes up a very small percentage of the emanation; petroleum absorbs a much larger percentage, and it is possible that by this method we can obtain a highly charged substance which can be taken internally. The majority of the radium waters used therapeutically contain an infinitesimal quantity of radium; yet good results are claimed to have been obtained by using artificially prepared radium water, in gout, rheumatism, arthritis deformans, etc.

The *Beta Rays* are sometimes described as soft and hard; the latter can pass through several millimetres of lead.

The *Gamma Rays* are very penetrating and require several centimetres of lead to stop their passage.

The proportion of these rays given off from a quantity of radium is relatively—

Alpha	*Beta*	*Gamma*
80 per cent.	9 per cent.	1 per cent.

In practical therapeutics it is possible to utilise the radiations from radium by taking advantage of what is known of its physical properties. If, for instance, we desire to use the alpha radiation, we resort to one or other of the methods already described. For external applications on superficial areas the beta rays are more generally used. The radium is fixed upon a flat surface which can be made any size or shape, it is incorporated in a varnish and can be diluted to the required percentage by mixing it with a salt of barium. A thin sheet of gutta-percha tissue is used to prevent damage to the radium. The exposure is calculated according to the needs of the particular case undergoing treatment. Filters of aluminium can be placed between the radium and the tissue. The thickness of the filter determines the percentage of beta rays which are allowed to pass through. The gamma rays are stopped only by the thickest filters, and in superficial applications they also act; but the percentage present is so small that for practical purposes they may be neglected so long as the exposure given is a short one; in other words, during the exposure necessary to get a reaction from the beta rays, the gamma rays would exert no appreciable effect upon the tissues, whilst if an exposure be given of sufficient length to get an effect from gamma rays, the effect of the beta rays on the tissues would be destructive.

When it is necessary to obtain the gamma ray effect the filtration employed requires to be thorough; nearly all the beta rays must be cut off. This can for practical purposes be achieved by a filter of 2 mm. of platinum or 4 mm. of lead. In order to prevent the action of secondary radiations induced by the radium rays upon the platinum filter, it is necessary to inclose the platinum tube containing the radium in a rubber tube.

In the manner indicated it is possible to utilise all three or any one of the three radiations according to the method employed and the degree of filtration used.

Radium has during recent years had an extensive use in the treatment of many diseases, and results are published from time to time which enable us to assess its value as a therapeutical agent. It may be stated that it acts in a similar manner to X-rays in a number of diseases, and in our own experience in the majority of such cases the effect is the same: though at times it is observed that radium acts well when X-rays have failed to improve the condition and *vice-versa.*

It is therefore hardly necessary to refer *in extenso* to the many diseases where radium has been tried and found useful. The practical point to be noted is that in cases where the results obtained are equal, X-rays should be given the preference when the cost of radium treatment is so great. There are, however, diseases on which radium exercises a more beneficial influence, and these should be specially referred to.

Vascular naevi, especially in young children, come under this class. The results obtained may be no better than those from carbon dioxide snow, but the radium method is painless. The treatment takes a longer time.

Rodent ulcer, if treated early, readily yields to thorough radium dosage. The scars produced are good. Recurrence is apt to take place if the treatment is not carried on for a considerable time after the lesion has healed. Even after thorough prophylactic treatment, recurrences may be met with.

Lupus vulgaris frequently yields to radium treatment after other methods of treatment have failed.

Radium has been largely used in the treatment of skin diseases, and marked improvement may take place in very chronic cases. Amongst these are chronic eczema, psoriasis, lichen planus, pruritus.

Papillomata respond rapidly to radium.

Leucoplakia responds readily to radium treatment. In situations such as the mouth, tongue, etc., radium is probably the best treatment which can be employed, largely on account of the ease with which it can be applied to the leucoplakia patch. This condition is frequently a forerunner or an accompaniment of cancer. When the latter disease has established itself, it renders the prognosis more grave, though very early cancer may be healed for a time at least. Prolonged treatment is necessary, and the radium applicator has to be well screened to avoid damage to the healthy tissues.

Radium in the Treatment of Malignant Disease

It is here that radium has found such a large field for its therapeutic properties. When first used in treatment, great hopes were entertained that at last we had an agent which would exercise a beneficial effect upon malignant disease and particularly upon cases of cancer. Enthusiasts in radium therapy spoke of the selective action of radium upon the cancer cell. That radium does exercise an influence over a morbid process in tissues no one will deny; but that it possesses a selective action on cancer cells only even its most enthusiastic supporter will now hardly affirm.

Many cases of all varieties of malignant disease have been treated with radium, some with benefit, others with none. Numbers may have been influenced in the wrong direction. We are still in the dark as to its exact action on these growths, nor can we foretell which particular case is likely to respond favourably to treatment.

Sarcoma, the round-celled variety, frequently responds well to radium. Such tumours may disappear after careful treatment, which should be continued for a considerable time to, if possible, prevent recurrence. Recurrence after operation has been successfully treated by long exposure to well-filtered radium dosage.

Lymphadenoma and *Lympho-Sarcoma* also respond to radium; but relapses are common with this as with other forms of radiotherapy.

Endothelioma is particularly amenable to radium treatment. When situated in the mouth or pharynx, radium is practically the only non-operative method of treatment we possess. The same applies to epithelioma and other forms of cancer. The tubes containing radium may be fixed in position and left for the necessary time.

Superficial Epitheliomata of the skin respond well to radium treatment, but there is the great drawback (which should always be kept in mind) that one can never tell when a particular case is likely to do well. Valuable time may therefore be lost if cases are treated with radium only. A good method is to excise the growth and treat afterwards with radium in the hope that recurrence may be prevented.

Cancer of the œsophagus may be treated by passing a radium tube into the stricture; the tube is kept in position by means of a length of silver wire which can be carried out at the mouth and fixed outside. Unless the radium tube can be passed directly into the stricture it is unwise to attempt to treat a case, because the healthy mucous membrane does not stand such long exposure as the growth, and serious damage may be the result of the treatment.

Cancer of the cervix uteri. When the disease is too extensive for operation to hold out any hope of relief, the condition of the patient may be greatly relieved by radium treatment. A preliminary curetting of as much of the growth as possible is helpful, the radium can then be carefully packed in position and the necessary exposure given. It is noteworthy that a marked diminution of the growth can be brought about by repeated treatment at regular intervals. Hæmorrhage may be checked, and discharge lessened. Several cases have shown marked improvement.

Cancer of the body of the uterus may be relieved by inserting radium tubes into its cavity. Recurrence of the growth after operation has occasionally to be treated, and the condition of the patient is frequently rendered more tolerable by radium treatment.

Cancer of the rectum may be treated by passing tubes into the stricture. Here, again, emphasis should be laid on the point that it is absolutely essential that the tubes should be placed in the midst of the growth. This can only be done when the lumen of the bowel is still patent and the growth involves the whole of the bowel. The growth shrinks and the function of the bowel may be restored for a time if a sufficient quantity of radium is used and a long enough exposure is given.

Recurrent cancer of the breast is treated by radium sometimes with a definite measure of success. In the majority of cases, however, X-rays do as much for the patient.

Inoperable cancer of the breast may be treated by several methods—

(1) External application of a number of tubes covering the whole area in sections giving an equal exposure to each.

(2) By inserting the tubes directly into the substance of the growth.

(3) By combined X-rays and radium treatment.

The writer has employed all three methods. Buried radium tubes have exercised a marked degree of action, but no individual case has resulted in cure.

One case treated by X-rays and radium cleared up and the patient remains well.

The degree of success attending the radium treatment of cancer is dependent on so many factors that it is at present impossible to make any definite statement on the point of its actual value. We can, however, state that slowly growing cancer which possesses a large percentage of fibrous tissue in its substance is more readily influenced than the rapidly growing cellular type. Some writers claim that the latter type readily responds to treatment. Rapidly growing cancer in young patients is hardly ever influenced by radium treatment.

The legitimate use of radium in the treatment

of cancer in the present state of our knowledge should be confined to—

1. Prophylactic treatment before and after operation. A few exposures can be given while the patient is waiting for operation. Tubes may at the operation be left in the wound and withdrawn after the necessary exposure. When the wound has healed, exposures should be given at intervals of about five weeks for a considerable time afterwards. Prophylactic treatment by X-rays appears to be as efficacious and is certainly more easily applied.

2. Cases of growth where the patient refuses operation should be treated thoroughly for a long period. It is in this group of cases that good results are occasionally met with.

3. Inoperable cases of cancer may by radium treatment be reduced to a state where operation is possible.

During the treatment of particular cases by radium the writer has been greatly impressed by the manner in which large masses of growth or large malignant ulcers have quickly disappeared, ultimately leaving a sound scar in place of the mass of growth. This seems to indicate that radium possesses a marked influence over the growth of these morbid processes. To a certain extent this is true, but in the adjoining skin which had been exposed to the radiations, new growth has appeared. A radium tube inserted into the newer growth quickly caused it in its turn to disappear. Later, however, large masses appeared at more distant parts. Observations of this kind raise the question of metastases—Did the radium stimulate the growth to such a degree of activity that its spread to distant parts was accelerated?

The local treatment of a growth does not appear to prevent its spreading in a number of cases. This may be due to the incomplete destruction of the cells of the growth. Further, it is just possible that unless the action of radium is very rapid and quickly kills all the cells, they may assume a marked degree of activity.

Observations of this kind suggest that in all cases of cancer suitable for operation the latter method should be employed and prophylactic treatment vigorously carried out afterwards, rather than run any risk of delay by experimental treatment by radium. The same routine treatment of malignant disease should be employed when using X-rays or radium. The most important point is to get the effect quickly, next, to prevent recurrence in the immediate vicinity of the local disease, the whole area of lymphatic distribution around the central area should be well irradiated in the hope that the tissues will resist further invasion. In some instances, if the exposure is too long or the filtration insufficient, a necrosis of the growth and the surrounding tissues results, all the tissues participating in the changes to a varying extent according to the power of resistance of the particular elements of the growth and the adjoining tissues. Thus, blood vessels become occluded, muscle fibres undergo a fibroid change and atrophy, nerve bundles become inflamed and later degenerate, mucous membranes slough, gland tissue becomes necrotic and the skin undergoes changes according to the intensity of the irradiation.

It has been observed on several occasions when patients have been subjected to long and repeated exposures that an extremely painful condition is set up in the neighbourhood of the tissues treated. This is particularly evident when the lesion is situated near the large nerve plexuses. It is probably due to neuritis and perineuritis of these large nerves and is troublesome and difficult to relieve.

In cancer of the breast treated by buried tubes in the substance of the growth, where the tumour has not yielded to radium treatment, or only partially so and a considerable degree of necrosis of breast tissue has followed with a degree of fibroid change, an intolerable amount of pain has followed. In one case the only remedy that could be suggested was the complete removal of the breast, and the severing of as many nerves as possible in the vicinity of the growth.

It should be always borne in mind in all cases treated by radium, where a considerable reduction in the size of a tumour has resulted, that, when it has been reduced to an operable condition, time may be saved and extension of the disease prevented if the radium treatment is combined with operative measures and prophylactic treatment is continued after the operation. R. K.

REST-CURES

The easiest thing in the world is to prescribe an orthodox rest-cure. It gives the physician rest as well as the patient. It saves all the worry and trouble of investigating fully an obscure case, and does away with the difficulties of individual treatment. In his well-known work on *Fat and Blood*, Dr. Weir Mitchell, referring to the form of treatment known by his name, says: "I am more fearful that it will be misused, or used where it is not needed, than that it will not be used, and, with this word of caution I leave it to the judgment of time and of my professional brethren." His prophecy was correct. The Weir-Mitchell rest-cure has become a stereotyped prescription, a conventional remedy that patients will even demand of their doctors themselves. We propose to describe very briefly the orthodox rest-cure, to analyse the curative elements that

it contains, and finally to discuss the types of cases requiring various forms of rest-cure. Weir Mitchell devised the rest-cure as a combination of psychic and physical influences, suited to the requirements of a fairly common type of neuropath. It comprises rest in bed, isolation, superalimentation, and massage. The typical routine is as follows—

7 a.m. Cocoa; cool sponge bath; rough rub.
8. Breakfast (ordinary full meal) with milk; an hour's rest.
10. 8 oz. peptonised milk.
11. Massage.
12. 8 oz. milk or soup; nurse reads aloud ½ hour.
1.30. Dinner (ordinary diet, two-course); 1 hour's rest.
3.30. 8 oz. peptonised milk.
4. Electricity; rest until—
6.30. Supper (ordinary diet, milk); rest.
8. Reading aloud ½ hour.
9. Light rubbing.

Weir Mitchell considered massage to be of the greatest importance in taking the place of exercise and counteracting the evils of prolonged rest, and on this account he preferred a bad rubber to no rubber at all. On the other hand, electricity was considered the least essential item in the prescription. A programme of this kind is calculated to act in a threefold way, on the emotions, the intellect, and the organism. The emotions are influenced by the isolation, it may be, from unwise sympathy or domestic friction. The intellect is influenced by inactivity, because no effort of any kind is permitted, and the body is affected by rest in the horizontal position, by diet and by massage. Now it is obvious that without more insight into the nature of our cases we cannot hope to determine successfully the exact therapeutic indications for each. There are some special characteristics of the neuroses to be considered which may serve as keys to treatment. The first thing is to decide whether the symptoms are purely defensive. Defensive symptoms have as their object the removal of the patient from an intolerable situation. The intolerable situation may exist in the material environment or may be due to the entry into the mind of ideas that are incompatible with the patient's personality. A man who finds his work uncongenial, or fears some element in it, may begin to exaggerate unconsciously some simple organic symptom until it becomes a successful defence against continuing that work. He passes from a transitory and accidental state of health into the organised neurosis. In the second eventuality the handling of the mental situation gives a greater range of results and reveals its final products in an infinite variety of ways of which the commoner are the obsessions, the phobias and the hysterical accidents. It must be borne in mind that it is useless to regard defence symptoms as due to fully conscious and wilful motives. Such an attitude only can lead to disaster. It is obvious that if a patient develops a defence symptom against an intolerable situation in the world, and is advised to take a rest-cure that three things at least may happen—

1. He may recover during the cure and relapse instantly when placed once more in the old situation.
2. He may be dominated by the idea that so soon as he recovers he will have to go back to the intolerable situation, and remain uninfluenced.
3. He may see things in a new light or find a solution to the problem during the cure, in which case he will speedily get well.

If a patient is suffering from a defence symptom that has arisen through moral conflict, and has freed himself from that conflict by the development of an obsession or other psychoneurotic manifestation, it is obvious that a pure and simple rest-cure is not likely to assist him. It may, and usually does, increase his distress.

From the above considerations alone it will be seen that it is important to gain some idea of the psychology of the patient before one can honestly prescribe a rest-cure. Since the state of mind is not apparent after testing the reflexes or examining the fundi, it is necessary to go into the patient's life history as fully as possible and urge investigation precisely in the direction of those matters which he seems least inclined to discuss. For this purpose it is a great mistake to force the patient to sit in a strong light. It is difficult for any one to talk of those factors that are powerful enough to produce defence symptoms and doubly so, if seated in the glaring light that convention usually associates with a medical examination.

The second factor to be considered is the amount of pain endured by the patient. Severe pain demands rest whether it be defensive in a psychological sense or defensive in the physiological sense of Hilton. But to Hilton's clinical conception of the importance of rest in pain must be added the view that pain may persist apart from material causes, and remain uninfluenced by bodily quiescence. Here one is apparently dealing with something that differs from inflammation. Pain may be persistent in a limb without any demonstrable modification of tissue. In such a case it will be unprofitable to direct treatment solely to

the prominent symptom, by the injunction of rest, and pay no attention to hidden factors. Mental tension, induced by worry, will express itself in many patients, particularly neurasthenics, in the somatic sphere by an aggravation of pain.

The third factor is that of nutrition. A condition of emaciation with its accompanying physical weakness is the most decisive signal for rest.

It is possible to summarise the above factors under two headings. Every patient presenting himself for examination must be considered from two standpoints, and his symptoms classified under two headings—

1. **Physiological Defence.**—By this is meant the normal reaction of the body to strain and exhaustion.

2. **Psychical Defence.**—By this is meant the special reaction of the patient's mind to his environment, and its expression in bodily and mental symptoms. The more fully (1) is represented, the more successful will the ordinary rest-cure prove. When (2) is chiefly present, the ordinary rest-cure will give very poor results. A person who breaks down through sheer pressure of work will present factor (1) most emphatically, and will derive benefit from rest. A person who breaks down owing to a tragic love affair will present factor (2) most prominently and will perhaps only be made worse by rest.

It will be seen, therefore, that for a large number of cases something more than simple rest, superalimentation and massage is required. Treatment can be directed, roughly speaking, in two ways. We may aim at increasing the patient's powers of resistance by discipline, re-education of attentive control, by suggestion, and persuasion. In this way we add something to the patient, and take nothing away. Or we may endeavour by a process of analysis to remove some of the patient's difficulties, and make clear to him how and why his troubles have arisen. By this method we take something away from the patient so that with his customary powers of will he is in a better position to handle the problems of his life. The comparatively small amount of insight that an average person has into the causes of his own behaviour or into the factors that produce a recurring and typical experience in his life makes psycho-analysis of great value. The aim of the analyst is not simply to tell the patient the nature of his difficulties, but to make him realise them for himself. The function of the analyst is to hold the mirror.

The emotional factor in the rest-cure requires special consideration. In neurasthenia the patient must be isolated from all sources of worry, strain, anxiety, perplexity and excitement. He generally needs a judicious amount of sympathy—indeed, many cases of neurasthenia, especially in young girls, are largely caused by lack of sympathy in the home or chronic conflict arising out of emotional antagonisms. The doctor tells her that she must "pull herself together," the mother has suggested that she should not think so much of herself, and the father has hinted that it is "all rubbish and hysteria."

In hysteria, on the other hand, the primary indication is isolation from sympathy. The hysteric must be removed from the possibility of causing excitement or commotion. She must be in an environment where hunger strikes cause no consternation and where broken windows arouse no amazement. In other words she must be removed from her audience and learn to appreciate the pleasure of a normal objective existence as opposed to her previous life of melodrama. But in this there is need for a word of caution. The genuine hysteric is convinced of her inability "to pull herself together." If she is treated with too direct discipline or scepticism, she will pose as the misunderstood martyr, and once this attitude of self-pose has been fairly established, we are very near the borderland of dual personality. Clifford Allbutt goes so far as to say that the Weir-Mitchell rest-cure is of no specific value in hysteria, except in so far as any removal from home and submission to medical discipline is effectual. The question of discipline is all-important. There must necessarily be a great deal that is distasteful to the hysteric in the monotonous seclusion of the rest-cure; and it is, therefore, of paramount importance that the doctor should feel that he has the necessary support and confidence of the relatives to enforce his authority. If the patient begins the cure "just to see what it is like" or if she feels that a pathetic appeal, or an insistent complaint would suffice to persuade her people to take her home, then the cure will be limited in its results. If it is necessary to humour the hysteric in order to keep her under treatment little can be achieved except in mild cases. There is no royal and pleasant road to develop inhibition. The doctor who shirks responsibility in this respect is simply neglecting a sacred duty, although he may be pleasing the patient.

On the other hand, the neurasthenic should, and will, enjoy a rest cure, provided it is conducted on rational lines. If she is a true neurasthenic and yet finds the cure irksome there must be something wrong with the cure. In the original Weir-Mitchell treatment what was chiefly wrong, from the point of view of the true neurasthenic, was the amount of time given to so-called rest, with no form of distraction.

The result was worry and increased introspection. This brings us to consider the intellectual aspects of the rest-cure. There are three lines of treatment in this respect—

1. Mental inactivity.
2. Mental occupation without effort.
3. Mental occupation with effort.

The Weir-Mitchell cure provides a great deal of the first, very little of the second, and none of the third, and it is in this respect that there is the greatest scope for adjusting the cure to suit the individual needs of the patient. We should ask ourselves how far the patient is capable of concentrating his attention, how far this degree of concentrative control is less than his normal power, how far the condition is due to undeveloped or deficient thought control, and how far due to overtaxed and abused concentration. The typical hysteric has little power of concentration unless in extraordinary circumstances. Volitional attention is of the weakest order. She lives in a chronic state of diffuse and spontaneous attention, with the threshold of consciousness abnormally low. Her power of determining her own area of consciousness is inadequate. This being so, re-education of the attention is essential, and the patient must be drilled in every form of exercise that will contribute to this end. The neurasthenic, for the most part, is unable to concentrate from sheer fatigue, and according to the stage of the complaint the indication is for absolute passivity, or for distraction without effort. Clifford Allbutt says: "In hysteria the key to successful treatment is active impulsion; in neurasthenia it is rest, rest, rest, in all directions but under such conditions as to avoid a cloying or rusty sluggishness."

Finally, we come to the physical aspects of the rest-cure. The first of these is rest in the horizontal position. In many cases this is clearly indicated, but there are cases in which the most perfect rest cure does not imply confinement in bed. Apart from neuropathic indications for prolonged rest in bed, we have to bear in mind such physical factors, incidental or concomitant, as circulatory insufficiency, gastroptosis, and floating kidney. In Weir Mitchell's original scheme superalimentation occupied almost the first place of importance. His views about fattening and blood-forming have for their foundation his abhorrence of drugs in any shape or form. One is often inclined to question the wisdom of this ruthless overloading of the stomach when some preparation of malt would go a long way towards fattening the patient, while injections of iron, with or without arsenic, would make up any deficiency in red blood-corpuscles or hæmoglobin. This is an item which should be adjusted to individual requirements and not blindly accepted as an integral part of all rest-cures. The question of massage, electricity and exercises must next be considered. Taking the cure as a whole, massage is imperative. Prolonged rest coupled with over-feeding would spell failure without it. But if the cure is modified massage may be wholly uncalled for. For the hysterical, it is best to avoid massage. She is apt to like it too much. Swedish and Müller's exercises answer better. As a rule we prefer electrical vibratory massage to manual massage. The value of electricity in neuropathic cases is chiefly suggestive, as most prominent electrotherapists admit. Static electricity seems to us to give the most satisfactory results but the indications are always empirical, and suggestion by itself, without cumbersome apparatus, is a simpler method of procedure. Exercises are of great value. They must be graduated, from mere Nauheim exercises to the most violent digging, and from croquet to club-swinging. The psychic element must be remembered in all work and exercise. Manual labour may be physically indicated, but it may be too monotonous to prevent introspection; walking may be indicated or otherwise, according to the companion available; motoring may be the cure of the man who drives himself, and harmful to the patient who is driven; dumb-bells may be used mechanically, but Indian clubs cannot.

For mental occupation card games are a great resource; Patience is almost invariably useful, and the ideal nurse should be able to teach the patient the varieties of this game. No burden must be laid on the memory of the neurasthenic. The contrivances known as jig-saw puzzles are valuable. Patients should be encouraged to do things in accordance with a self-imposed time-table, and be independent of their feelings of fitness or otherwise. The time-table should be made out every evening for the following day. This increases self-confidence.

As regards the nurse, the greatest mistake she can make is to fall into the error of professionalism. The solemn and sacred rite of taking pulse and temperature with an air of mystery is a sweet morsel to many a hysteric, in whom the doctor is trying to inculcate some degree of healthy-mindedness.

We have surveyed as briefly as possible the general aspects of rest-cures. The particular methods of treatment applicable as adjuncts during the cure are discussed in other articles. Both in suggestion and psycho-analysis we have two powerful weapons with which to combat the graver cases of neuropathic disorder. In conclusion we mention a few points of success and failure. If an hysterical patient is treated as a neurasthenic, the results will be transitory.

If a neurasthenic is treated as a hysteric, there will probably be no results at all. If a case of neurasthenia due to eye-strain goes through the orthodox cure, he will improve rapidly at first, slowly towards the end, and relapse instantly when he resumes work. Many rest-cures are begun, endured and paid for, that might have been avoided by seeking the advice of a competent oculist. All cases of toxic neurasthenia tend to improve chiefly on account of the massage, but there is little to boast about if one cures for the moment a patient who should have had a vaccine for some hidden suppurative process. Finally, the aim of every rest cure should be not only to put the patient on his feet again, but to teach him never again to fall; and to do this two things are essential—the avoidance of routine and the most careful and painstaking study of the psychology of each case.

TREATMENT OF THE SPECIFIC INFECTIOUS DISEASES

THE GENERAL TREATMENT OF INFECTIOUS FEVERS

The fevers included in this section are **Chickenpox, Diphtheria, Measles, Mumps, Rubella, Scarlet Fever, Smallpox, Typhoid Fever, Typhus** and **Whooping Cough.** Cerebro-spinal Fever only receives notice in regard to prevention, as its clinical aspect is dealt with elsewhere. Being a very doubtful entity, the "Fourth Disease" is not mentioned. Repetition throughout the section is avoided by treating common points collectively and noting special ones as they arise. So considered, the subject falls naturally under eight heads: beginning with (1) prevention, the others are the treatment of the infective process by (2) specific means or (3) chemical germicides; (4) of local lesions, mainly by antiseptic applications; (5) of the febrile disturbance; (6) of related factors in this disturbance; (7) of cardiac weakness by direct measures; and (8) of the post-febrile state.

I. Prevention

1. The Control of other than Clinical Sources of Infection.—Such sources, the habitats of pathogenic germs, are, with possible rare exceptions in certain fevers, either carriers or contacts liable to develop an infection. Temporary carriers of the diphtheria bacillus, the meningococcus, or the typhoid bacillus, may be isolated in special circumstances, but the rule is to warn all carriers as to the modes of direct or indirect contact which may be dangerous to susceptibles, and to employ local antiseptics for what they are worth when the organism concerned is the diphtheria bacillus or the meningococcus. Contacts kept under observation over the quarantine period of a fever need seldom be isolated. In *Diphtheria*, with some uncertainty of result, antitoxin prevents the development of an attack and is used for children, but for adults it has the disadvantage that serum sickness may keep them from work for a week or even longer. When a case of *Smallpox* occurs, any unvaccinated infant or person in the house should at once be vaccinated, and all adults and younger persons over the age of eight revaccinated. For about three days after exposure, vaccination will usually avert the coming attack if infection has taken place. In practice, all contacts are vaccinated so long as symptoms of an attack are absent. Strict isolation and disinfection are ordinarily reserved for actual cases of the various fevers.

2. Isolation in Hospital.—*Smallpox* is removed to a special institution on a secluded site. Regularly or incidentally admitted to fever hospitals, the other diseases are for the most part segregated with their kind in large wards and there nursed in common. However, by complete or partial separation with asepsis, or by means of the latter alone, it has been found possible to utilise the same nursing staff for diverse infections. Such methods of unit nursing include the barrier system, bed isolation, and the use of cubicles, corridor cells, veranda cells, and open-air shelters. Tests with some fevers have not passed the experimental stage, but the available evidence is to the effect that when the beds are at a sufficient distance from each other, asepsis alone will control all those in view, except *Scarlet Fever, Measles* and *Chickenpox*, if fresh air is supplied freely. The non-convection of the last three by the air of well-ventilated wards, and the possibility of safeguarding susceptibles from their virus when carried by other vehicles at close range, must remain an open question until the observations of Rundle and Burton at Fazakerly Hospital are tested further or proof is obtained by some other method of investigation.

3. Isolation at Home.—The quarters chosen, including a room for the nurse, and, if possible, a bathroom and w.c., should be at the top of

the house or in a passage which can be closed to the family. They should be stripped of furnishings to the hospital standard and barriered off from the rest of the house by a suspended sheet kept moist with 1 in 60 carbolic lotion.

4. **Disinfection.**—Subject to supervision by the medical man, this, of course, is entirely in the hands of the nurse. She works in four zones—

(A) *At the source.*—The points at which discharges leave the body are in most instances determined by the location of inflammatory tracts, and it is the rule to treat all such discharges as infective. With exclusive isolation, however, their control in *Smallpox* at this stage is more a matter of cleanliness than prevention. (*a*) The *nose* and discharge from it are chiefly treated in *Cerebro-spinal Fever*, nasal *Diphtheria*, *Measles*, *Scarlet Fever* with rhinitis and *Whooping Cough*. The nasal cavities may be sprayed from time to time with an antiseptic while gross discharge is frequently swabbed away from the nostrils. (*b*) Discharge from the *mouth* may be due to stomatitis, or to the sore throat of *Scarlet Fever*, *Diphtheria*, etc. A syringe clears out the mouth and throat most effectively. If there is a trickle from the mouth, it is removed by swabbing. Sputum, as in *Whooping Cough*, is collected in a spit-cup containing 1 in 20 carbolic lotion or on a piece of rag, afterwards burnt. (*c*) The *ear*, in the otitis of *Scarlet Fever*, *Diphtheria*, etc., is syringed out and at other times covered with absorbent wool. (*d*) The *eye*, when discharging in *Smallpox*, etc., is washed with a mild antiseptic and, if necessary, an absorbent dressing applied without pressure. (*e*) The *skin*. Milne maintains that *Scarlet Fever* will not spread under any conditions of contact if, from the outset of an attack, firstly, the tonsils and pharynx are swabbed with carbolic oil (1 in 10) every two hours for twenty-four hours, and, secondly, pure eucalyptus oil is rubbed over the entire skin every morning and evening for five days and then once a day until the tenth day. The method has failed at Plaistow Hospital, where early treatment is seldom possible, but in view of the evidence adduced in its favour, the writer considers it well worth a trial in private practice. *Measles* has been similarly treated. Secondary cutaneous sores, most frequently caused in *Scarlet Fever* and *Diphtheria* by irritating discharge, are covered with a dressing, unless their position on the face makes this impossible, when they are thickly smeared with lanoline or some ointment. As infective sources, their prevention is important. (*f*) The *anus and urethra*. It is only in *Typhoid Fever* that the disinfection of excreta is attempted in this country. The standard proprietary germicides which emulsify with water are more reliable than carbolic acid for this purpose. Half-an-ounce, with about twenty times as much water, may be put in the bed-pan. Two drachms, undiluted, are added to ten ounces of urine: more or less in proportion. If crude carbolic acid is employed, the quantities are the same; it is placed, pure, in the bed-pan or urine bottle when the utensil is taken from the bedside. All germicides are stirred through the fæces or urine with a piece of stick, which is then burnt. An hour is supposed to be allowed for their action before the utensils are emptied, but in practice the nurse is commonly compelled to dispense with this precaution. Moreover, disinfection at best remains uncertain, and the destination of the excreta is thus more important. In a sewered district there is no objection to discharging excreta into a w.c., and this course is usually taken. Burial, again, may be the only available resource in the country. Where there are no sewers, the disposal of evacuations during an epidemic is a question for the Local Authority; they may be collected and buried or burnt. Urotropin as a vesical disinfectant is mentioned in Part II. (*g*) Inflammatory discharge from the *vagina* is rare, but least so in children who have *Scarlet Fever*. It is controlled by disinfection and an absorbent pad.

(B) *On the bed.*—For all the careful collection of visible discharges and the use of check splints to keep children from dabbling in those coming from the mouth, nose, eyes and ears, a portion is certain to escape and reach the bed, which is also exposed to particulate impregnation. Thus the bed becomes, as it were, a trap for the contagium which passes the first zone, and is placed about eighteen inches from the wall to prevent the patient from touching the latter. When discharge comes from the mouth or nose, or there are uncovered sores about the face, gross soiling of the pillow is guarded against by using an inner case of jaconette or batiste. Fever patients who have discharges should wear a linen or cotton nightdress rather than a woollen one; a vest of wool will serve as additional clothing and can be sleeved if needful. The mattress, in the case of young children and older incontinent patients, is protected by a mackintosh under the sheet. Over the latter a drawsheet, folded to form a broad strip, crosses the bed with its centre under the buttocks. A hospital drawsheet is single; for *Typhoid Fever* with diarrhœa, it has a narrower mackintosh under it. A sheet is always placed next to a patient who passes excreta in bed, as it partially saves the overlying blanket from contamination, and the

nightdress is slit all the way up the back. Taking these coverings as a whole, their object is not only to facilitate the collection of discharges, but to make changes less tiring for the patient and easier for the nurse, and to give less work in disinfecting and washing.

(C) *On or in vehicles away from the bed.*—*Cerebro-spinal Fever* and *Rubella* are not known with certainty to infect indirectly, and the other acute infections, with the exception of *Typhoid Fever*, are more often contracted during close association with patients than carried deviously by vehicles. Nevertheless, all contaminated articles are disinfected. (*a*) The nurse's hands have constantly to be cleansed in the course of her work, and she has to protect her uniform from gross soiling, if need be, by wearing an overall. (*b*) Some crude carbolic acid or other disinfectant is added to waste syringing and douching solutions not in themselves definitely germicidal. Water which has been used for washing and bathing is similarly treated, especially if the disease be *Typhoid Fever*. (*c*) Dressings, swabs, etc., are burnt, with such used food and rubbish as are combustible. (*d*) Stains caused by discharges and excreta are washed out of cotton, linen and woollen articles, including blankets, by pouring water through the soiled part into a bucket, w.c., or, in hospital, a hopper. Linen and cotton articles, with others of the same kind not visibly soiled, are steeped in an emulsifying disinfectant (1 in 40), well rinsed in pure water, and boiled at the time of washing. Woollen clothing and blankets, after stains are removed, have only the cleansed parts exposed to the disinfectant by laying them over a bucket containing it. They are not steeped as a whole or boiled. (*e*) Suitable articles (medical, surgical, nursing) are sterilised by boiling. (*f*) As water carries the contagium of *Typhoid Fever*, that required for the household may have to be boiled, especially if the local supply or public service is under suspicion. (*g*) *Diphtheria*, *Scarlet Fever* and *Typhoid Fever* are spread by contaminated milk. Hence, when the source is doubted, it is boiled, and in any case the supply for a family should be separately stored from that used for a patient. Hospital nurses should not be allowed to take food, milk, beverages or water, while on a division used for cases of Typhoid Fever. If they become infected, it is generally found that this rule is not enforced or has been broken. (*h*) Flies are difficult to control, and as they are attracted by discharges both at the source and as carried by vehicles, seek out food, and may settle on the face of susceptibles, it is reasonable to believe that they transmit infections. Fly-papers and fly-traps are almost useless unless open windows are screened with gauze and doors kept closed. Flies may be kept off patients who have discharges or sores in the region of the face and head by attaching one edge of a gauze square half-way up the head-rails and fixing the opposite side to the chest. If the infection is one borne by milk (par. *g*), vessels containing it should be covered. In *Typhoid Fever*, all stored food should be so protected, bed-pans and urine bottles covered until they can be cleansed, and the exposure of stained linen, etc., avoided. The prompt burial of excreta in country practice is also indicated; typhoid bacilli have been found in flies. (*i*) Air may be a vehicle of *Diphtheria* and doubtless also of *Measles*, *Whooping Cough*, *Scarlet Fever*, *Cerebro-spinal Fever* and other diseases, when patients or carriers cough, sneeze or speak (droplet infection). Medical men and nurses have to be careful in this respect when close to patients. As regards what may be termed atomic dispersal of virus, the existence of which it seems necessary to accept, free ventilation is apparently an all-round safeguard, though more effective in some diseases than others. It is largely relied on to protect medical men and nurses from *Typhus*, now commonly treated in the open air. (*j*) Transference by third persons, other than medical men, nurses and carriers, is prevented by strict isolation, but in actual fact normal contacts are infrequent vehicles, except possibly in the case of *Smallpox*.

(D) *At large in the sickroom or ward.*—It has still to be proved that infection due to germ-laden dust, if it does occur when a fever has a relatively resistant virus, is common. Meanwhile all dust is treated as infective. At one end of transference, the nurse is expected to remove fouled articles before gross discharge can dry. At the other, she should, before sweeping a ward, scatter some damp substance on the floor; in a private house, cover her broom with a cloth wrung out of 1 in 20 carbolic lotion and use a duster similarly damped.

5. **Periods of Detention.**—In *Cerebro-spinal Fever*, the meningococcus is rarely present in the naso-pharynx when two months have passed from the commencement of an attack, and has usually disappeared long before this period, but as more persistent convalescent carriers exist, a bacteriological examination should be made before patients are released, and conditions laid down if the germ is found. Cases of *Chickenpox* are free from infection when all scales and scabs have come away. Persistent lesions which have lost their first crust are very rarely infective. Those recovering from *Diphtheria* are held to be possibly infective so long as the discharge and sores due to it persist, unless the bacillus is shown to be absent from these lesions, and until three successive cultures from the nose and throat

prove negative. However, even in the absence of the culture-test, return cases are extremely rare in hospital practice. Three weeks' isolation is usual in *Measles*, and the period may be prolonged by persistent catarrh or pneumonia. For *Mumps*, the same period from the setting in of the glandular inflammation is enough; for *Rubella*, a fortnight as dating from the outset of the eruptive stage. As a rule, straightforward cases of *Scarlet Fever* have lost their infectivity at the end of four weeks, but in this disease no criteria are known on which to base a safe opinion as to the absence of contagion then or later. It is, therefore, even at the present time, the rule to isolate cases for six weeks from onset, and for any longer period occupied by primary desquamation. This serves to cover an undue extension of the infective stage in some uncomplicated cases. Peeling of the hands and feet may be quickened by scrubbing them with a nail-brush, soap and oatmeal. Towards the end of desquamation, the feet are commonly steeped in hot water every evening; some permanganate of potash may be added. On the positive side, certain minor sequelæ are held to show a possible persistence of infectivity. Hence, in examining patients, the clinician should satisfy himself that: (A) there is no sore-throat; (B) the nose and ears are not discharging; (C) the inside of the nostrils, as far back as can be seen by ordinary inspection, are not inflamed or excoriated; (D) there are no cracks or sores about the head, including the region round the nostrils, the angles of the mouth, the folds of the ear with those behind and below it, and the scalp; (E) other parts of the skin, especially along the nails, between the toes and about the buttocks, are not inflamed or broken and suppurating. Persistent nasal and aural discharge are troublesome features when further detention is in question. Return cases are rarely referable to ear discharge after three months, but the outlook is less certain in rhinitis. In general, coincidence has to be allowed for when infection seems to arise from any discharged patient. The infection of *Smallpox* has gone by the time all crusts have separated and any sores are healed. Daily warm baths and, later, the steeping of the feet every evening in hot water, will aid decrustation. Hard masses sunk in the epidermis of the soles can be carefully detached with a blunt-pointed knife. In modified cases, with little or no crusting, the minimum period of isolation is three weeks; the mean period for average cases is about eight weeks; the maximum covers some months. In *Typhoid Fever*, isolation ends when the patient is fit to go about, and even in the acute stage it need not be stringent as regards visitors who merely come and go. The practice of examining the fæces and urine to ascertain if convalescents are carriers and should take certain precautions has not yet been generally adopted. *Typhus* cases are isolated for not less than four weeks. *Whooping Cough* seldom spreads when the spasmodic stage is definitely declining, but the safest plan is to maintain strict isolation until then, and thereafter to prevent direct contact with children until the whoop has gone.

6. **Precautions on and after Discharge.**—As the time of release approaches, patients should be in the open air every day when practicable and have a warm bath in the evening. Then a final bath is given and the hair thoroughly washed. If the disease be *Diphtheria* or *Scarlet Fever*, the patient should keep away from children for a week and sleep alone for a fortnight after discharge. After Scarlet Fever, children should not attend school for a fortnight, and for any further time required to make two months from the onset of the attack; after Diphtheria, for a month, unless the culture-test has thrice proved negative.

7. **Final Disinfection of Premises and Furnishings.**—The nurse burns valueless articles and sterilises others with a germicide or by boiling them. The local authority may remove the bedding for steam disinfection; without such treatment, the passage of time with exposure to air and light will alone render it safe in some fevers. Fumigation of the quarters is practically useless. The floor, woodwork and furniture should be thoroughly swabbed with 1 in 20 carbolic lotion and scrubbed later on with soap and hot water. It is usual to have the sick-room repainted and repapered.

II. Specific Treatment

1. **Infection,** as a method, is only represented by vaccination against *Smallpox*. Although essentially preventive in aim, it may modify the disease if performed within the first five or six days of incubation. Unless exemption is claimed under the Act in the first four months, infants must be vaccinated within six months of birth, provided they have not had Variola or are not medically certified as unfit subjects physically or owing to their home surroundings or possible exposure to infection. About one child in four is not vaccinated, and the present immunity of the country, subject at any time to failure locally, is referable to the protection of the majority, to emergency vaccination when Smallpox occurs, to the control of contacts, to care in the identification of modified cases, and to a costly system of hospital isolation. The crux of the case for vaccination is the right of its advocates to lay down the conditions under which it will do all that is claimed. These

conditions are, firstly, efficient inoculation, and, secondly, its repetition.

(A) Efficiency depends on three factors. (*a*) The lymph must give rise to the typical lesions of Vaccinia. Assuming the source to be satisfactory, there remain in question its freshness, the technique of inoculation and the clinical characteristics of the lesion. (i) Glycerinated lymph, kept cool and in the dark after issue, retains its full activity for about two months and deterioration during the next five or six is not ordinarily enough to render it inactive. If any home-stored lymph fails to infect, a freshly issued supply should be used. Even such a lymph may fail, although very rarely, and another strain can then be tried. Not until three tests with active lymph have proved negative is the subject to be regarded as immune. Three failures exempt a child under the Act. (ii) In inoculating lymph, the arm is washed with soap and water and afterwards with boiled water. Some distance below the shoulder, the lymph is spread over areas equal to the intended insertions. The areas are superficially scratched with the blunt point of a sterile scalpel or lancet in close, crossed lines. The arm being exposed to the air, ordinary lymph soon dries, but glycerinated lymph remains slightly moist and should be given half-an-hour to penetrate. Finally, a pad of aseptic gauze and wool may be bound over the part with cross-straps of oxide of zinc plaster. (iii) In three days the areas show some redness and swelling, and two days later have begun to change into vesicles. This change reaches its height on the eighth day, when the vesicles are well filled, flattened, depressed centrally, and have a red areola. Pustulation, setting in now, may be accompanied by two or three days of slight fever and axillary lymphadenitis. Maturation is complete by the tenth day. Meanwhile, redness and swelling have spread about the insertions and, exceptionally, may involve the whole length of the arm. On the eleventh day, desiccation is apparent. It ends in the formation of a crust which ordinarily comes away in the third week. The red scar blanches in time. Subsidiary vesicles occasionally develop near the primary ones, but a general vaccinal eruption is rare. Non-specific rashes, roseolar, urticarial, possibly vesicular, occur in a very small percentage of cases. (*b*) The term of immunity is directly related to the number of insertions. Four should be made, half-an-inch apart. A newborn infant exposed to Variola, or a person who is a weakling or an invalid, is acutely ill, or is suffering from some cutaneous affection, can be safeguarded for the time by one insertion. Otherwise the rule should not be varied. (*c*) The term is also proportionate to the area inoculated. Taken together, the insertions should cover at least half a square inch. As a record of efficient vaccination, besides the number and whole area of the scars, pitting is taken into account. Very smooth, superficial cicatrices suggest that the vaccinal lesions were ill-developed. In any case the scars tend to become less sharply marked with the passage of time.

(B) The protection afforded by vaccination in infancy is less persistent than that conferred after childhood ends, when it is more likely to continue in some degree through life. Consequently, revaccination at the age of twelve is requisite to maintain resistance, but all that is done in this direction in England is to make it free at the hands of the public vaccinators. In an epidemic, all adults should in any case be revaccinated whether they are contacts or not. As to the chance that a second infection may be transmitted—an issue greatly exaggerated by opponents of vaccination—for cancer and leprosy, if not tuberculosis, it may be regarded as hypothetical. Eczema may become active or extend more widely after vaccination, but its determination is less certain. Even with affections of the septic group which are readily acquired (suppurative conditions, erysipelas, impetigo, etc.), the danger is inconsiderable in view of the vast number inoculated without any untoward result. Undoubted instances of inoculated syphilis, again, are excessively rare. Under most conditions, an added infection may be merely coincident, and with the passing of arm-to-arm vaccination syphilitic infection is losing its significance even for the purposes of controversy, as, in a less degree, are the other affections mentioned. This method is therefore to be avoided, but if circumstances should make it needful, the lymph is obtained on the eighth day from a healthy subject vaccinated for the first time, and is taken from typical, unruptured vesicles. The purity of calf-lymph is further ensured by mixing it with glycerine, which greatly reduces the number of extraneous organisms or causes them to disappear. The glycerine requires time to act, and to meet this condition and the eventual loss of virulence, supplies may be dated by the makers to show the period within which they are usable. Lymph is also purified by treating it with chloroform.

2. **Vaccine Treatment.**—See article on Principles of Vaccine and Serum Treatment for various details. In *Diphtheria*, vaccine has been used to a limited extent to prevent the carrying of the bacillus or to treat actual carriers. It is suggested that the injections should begin when the local lesion is retrogressing. Hewlett and Nankivell employed a filtrate containing the endotoxin: two milligrams, doubled after a week and repeated at similar intervals if the

germs persisted. At Plaistow Hospital an autogenous vaccine of dead bacilli has been tried in a few cases: average weekly doses, 100, 200, 400, 800, 1,200 and 1,600 millions. Viewing known results, the carrying stage seems to be shortened in some instances, but the treatment may fail and its utility is not established.[1] Forbes and Newsholme tested autogenous vaccine (doses 5 millions to 400 millions) in nasal Diphtheria. The rhinitis declined, but bacilli persisted in the affected tract. Strong evidence comes from Russia, where Gabritschewski and others have inoculated many thousands of individuals with a streptococcic vaccine derived from a case of *Scarlet Fever*, that his medium is protective and of value in epidemics. It consists of concentrated bouillon culture: minimum dose, if based on age, 0·25 c.c.; maximum, 1 c.c. Three injections are made at a week's interval, the second and third doses being increased by half or doubled. Watters, treating nurses a fortnight or longer before exposure with a polyvalent streptococcic vaccine cultured from patients, in doses of 50, 100 and 200 millions at weekly intervals, observed a reduced attack-rate. Although reports conflict, it appears that autogenous vaccines may benefit patients in the acute stage. Jochmann and Michaelis advise the associated administration of antistreptococcic vaccine and serum. In carrier cases of *Typhoid Fever*, fæcal and urinary, vaccine treatment has proved disappointing, although a few successes are reported. Vaccines have been largely employed to immunise susceptibles. Wright's preparation, consisting of bacilli killed at 60° C., has, in particular, found a wide application in the protection of troops. Its efficiency is generally admitted. Two doses are injected, the first of which may be 500 millions, the second, given ten days later, 100 millions. Statistics show that the treatment lessens the chance of infection and of cases proving fatal. Besredka's method of sensitising vaccine by treating it before use with antibacterial serum applies in Typhoid Fever, and, considering experimental results, its adoption in the treatment of acute infections more generally, to produce rapid immunity and to cure, is a probable development. Broughton-Alcock has used a sensitised living vaccine in the prophylaxis of Typhoid Fever. Clinically, ordinary stock and autogenous vaccines seem to do good in doses of 50 millions, rising at intervals of three or four days to 500 millions or more. Callison has given larger doses: 500 millions increased by 100 millions every fourth day. Schäfer makes remarkable claims respecting the curative effect of his vaccine. In 150 cases he had only four deaths. There is ground for the view that a vaccine of Bordet's bacillus is serviceable in the prophylaxis and clinical treatment of *Whooping Cough.* Freeman has defined the best average dose as 100 millions. In the first year of life 25 millions may be given, in the second 50, and thereafter 100, with smaller doses of the influenza bacillus and pneumococcus, as these organisms are so constantly present and are concerned in the complicating pneumonia. To protect, the simple or compound vaccine may be injected thrice at weekly intervals, the second and third doses being doubled. Clinically, the average dose may be continued as required, week by week. In the *local affections* which complicate or follow certain fevers, as rhinitis, otitis media and cutaneous sores caused by their discharges, present results point to a useful field for vaccine treatment; such obstinate lesions may rapidly improve, quickly heal, or run a shorter course, although failure is common, particularly in otitis media. Streptococci, staphylococci, diphtheria bacilli and diphtheroid organisms are mainly found in these infections, and autogenous compound vaccines prove more effective than those from stock strains. At Plaistow Hospital no attempt is being made to separate the different germs in cultivating them: doses, 100, 200, 400, 800, 1,200 and 1,600 millions at seven-day intervals. As a general principle, the treatment should commence before chronicity is established. A vaccine of the related streptococcus is said to influence scarlatinal nephritis favourably.

3. **Serum Treatment.**—See also p. 57. In *Diphtheria,* antitoxic serum (2000 units) is given to protect contacts; its effect, said to last two, three or four weeks, is uncertain. As a curative agent, the serum is life-saving both in the faucial and laryngeal forms of the disease, and reduces the severity of non-fatal faucial cases. Nowadays heroic doses are avoided. In faucial infection with only a trace of membrane, 2000 units suffice, subject to repetition on the following day if the membrane is growing. With the tonsils partly covered on the first or second day, this dose is enough and can be repeated in twelve hours. When they are entirely covered, 4000 units should be given on the first or second day, and the same dose after the above interval; if two days have passed or there is nasal discharge, 6000 units are repeated. Should the membrane spread in these instances, a third dose is indicated. With thick membrane covering a wider area than the

[1] Scholtz' application so far promises better than vaccine treatment. A 24 hours' broth culture of s. aureus is sprayed on the throat every two hours or less frequently. The diphtheria bacillus may disappear quickly. Septic infection is unusual and nearly always slight. The broth may be swabbed as well as sprayed on to the mucous membrane.

When children are carriers, hypertrophied tonsils and postnasal adenoids may require removal.

tonsil, but not the palate extensively, 6000 units repeated twice are usually sufficient, unless nasal discharge is marked or the fourth day is reached, when 8000 units are required. This last is now the regular maximum dose for all severe cases in any stage, but if there be much palatal exudate it is sometimes raised to 12,000 units. In laryngeal cases, 8000 units are given twice or thrice at twelve-hour intervals, according to the degree of obstruction and the amount of membrane in the pharynx. Although early administration is needful to obtain the full effect of the serum, the dose has to be greatly increased as time passes, and after some days little or no benefit is said to accrue from its use, the writer does not care to withhold antitoxin so long as any membrane is present. Antitoxin saves some early cases of diphtherial croup from operation, and with operation has reduced the case-mortality to about 1 in 3, much better results than this being obtained in some series. Acute diphtherial rhinitis, rare as apart from faucial infection, is treated with maximal doses if severe. Sub-acute and chronic rhinitis is a common sequel of the acute form, and diphtheria bacilli are not rarely present in the nasal discharge following Scarlet Fever. If antitoxin has already been used in the former instance, its repetition is contra-indicated; otherwise, and in the latter, moderate doses may reduce the discharge, but this effect is apt to be transient and serves chiefly as an adjunct to vaccine treatment and local antiseptics. Diphtherial conjunctivitis, an uncommon infection, usually shows quick improvement under antitoxin treatment. Large doses should be given if membrane forms, or the eye may be destroyed; fatal cases are recorded. Wound diphtheria responds to antitoxin. Chronic diphtherial dermatitis, oftenest impetiginoid in its features, is commonly very resistant to non-specific treatment, whereas antitoxin promptly clears up some cases and improves others. In *Scarlet Fever* with a frank septic element, antistreptococcic serum in large doses (50 c.c.) appears now and then to be useful, but its action is unreliable. Cumston, employing a polyvalent serum prepared by means of streptococci from cases of the disease, considered the results favourable. The efficacy of other special serums (Marmorek's, Moser's, Aronson's) has not been proved beyond question. The value of serum taken from convalescents and of diphtheria antitoxin in Scarlet Fever and *Typhoid Fever* is doubtful. In the latter fever, ordinary antibacterial serum has been supposed to confer a passing immunity. Curatively, it is a failure. Chantemesse states that the case-fatality of the disease has been reduced to less than 5 per cent. by his special serum, given in doses of a few minims, repeated once or twice. Wright is of the opinion that it may act as a vaccine. Macfadyen and others prepared an anti-endotoxic serum, which is the medium, in theory at least, likely to prove effective. Hewlett also adopted this method of preparation; the serum did no apparent harm and seemed to influence the disease favourably. Forssman's and Ludke's limited observations with doses up to 50 c.c. bear this out. Lieuriaux' serum for *Whooping Cough* was stated by him to be beneficial; the same claim has been made for serum from convalescents. Serum from vaccinated heifers has been injected in *Smallpox;* also that obtained from convalescents. Their effect remains in doubt.

III. Treatment by Chemical Germicides

Local antiseptic applications (see Part IV) seem sometimes to influence septic infection, but their effect on the specific lesions of the fevers is inconsiderable, that of faucial *Diphtheria* being a possible exception. By the mouth, salol (10 gr. four-hourly in fine powder) renders the eruption of *Smallpox* less foul and markedly reduces the cutaneous irritation in many instances during the developed stage and decline. Haller has administered salvarsan in four cases and advises its early use to modify the rash. Prescribed internally in the specific bacilluria of *Typhoid Fever*, urotropin (10 gr. thrice daily in an ounce of water) sterilises the bladder in less than a week, and most cases of actual cystitis are quickly cured; but if bacilli of the colon type are present in the latter affection, it may resist the treatment. When given for bacilluria, the drug is continued for ten days. It causes a fall in the number of bacilli in chronic urinary carriers, but there is an increase when it is withheld. Two apparent cures in which borovertin was prescribed are reported.

IV. Local Treatment

It will save space to state here that in the treatment of certain local lesions (rhinitis, otitis media, cutaneous sores) the principle is to employ agents that are antiseptic, astringent and stimulating. As a rule, irritation is avoided, and as the response varies with the case, the strength of a given application may have to be altered or another agent chosen. When improvement ceases, it is often advisable to change the treatment. Again, two applications may be used alternately, each for a few days. In chronic cases, all stimulating applications should be stopped after a time to ascertain whether they are not acting as irritants and prolonging inflammation.

1. **The Mouth.**—In severe cases of fever, the nurse cleanses the teeth, gums and tongue after the two-hourly feeds during the day with

some such mixture as the juice of a lemon and an ounce each of glycerine and peppermint water. For simple, aphthous and mild ulcerative stomatitis the mouth may be swabbed every four hours with undiluted glycerine of borax. If there is definite ulceration, it should be first syringed with a saturated solution of boracic acid; in painful cases, with 1 in 40 carbolic lotion, which the patient, however, must not swallow. Or, where pain prevents both syringing and swabbing, a spray of carbolic solution (1 in 20) may be substituted. Ulcerative stomatitis of the destructive type is an occasional complication of *Septic Scarlet Fever* and occurs, more rarely, in *Measles, Typhoid Fever* and *Typhus*. It is usually treated by syringing with chlorine water. To make this, five drachms of powdered chlorate of potash are placed in a large stoppered bottle and fifty minims of strong hydrochloric acid added. Chlorine gas is given off and displaces the air. In small quantities at a time, with frequent shaking, thirty ounces of water are poured into the bottle to make the solution. If the ulcers continue to spread, they may be touched with carbolic acid while the patient is under ethyl chloride. Gangrenous areas may have to be scraped and stippled over with strong nitric acid. Open-air treatment is indicated in such cases.

2. **The Fauces and Pharynx.**—Sore throat is met with in most of the fevers: as the local lesion of *Scarlet Fever* and many cases of *Diphtheria*, and, with varying severity, as a regular or occasional feature of *Measles, Rubella, Smallpox, Typhoid Fever, Typhus* and *Whooping Cough.* In all forms of tonsillitis and pharyngitis a very common prescription is—

℞ Tinct. Fer. Perchlor. ♏ x
Glycerin. ♏ x
Aq. ad. ʒ ii

thrice daily or four-hourly for a child of four. The writer prefers to exclude chlorate of potash from this formula. As a local application when the affection is mild, with little or no discharge, tablets containing formaldehyde offer a convenient means of treatment if the patient is not a young child; one is allowed to dissolve in the mouth every two hours during the day. Sucked drugs are, however, contra-indicated when there is much discharge. A gargle may be sufficient for catarrhal cases after childhood—

℞ Formalin. ♏ i
Aq. ℥ ss;

Liq. Pot. Permang. ♏ x
Aq. ℥ ss;

Acid Carbol. Liq. ♏ ii
Glycerin. Borac. ♏ x
Aq. ad ℥ ss;

or—

Hydrogen. Perox. Liq. ʒ ss
Sod. Chlorid. gr. ii
Glycerin. ♏ xv
Aq. ad. ℥ ss

To control infective discharge, to prevent the patient from swallowing it, to minimise sepsis, and to make respiration less difficult when there is faucial and nasal obstruction, the throat is syringed four-hourly or thrice daily with boracic lotion. No other method is so cleansing, and the statement that it may cause otitis media is not borne out by comparative observations at Plaistow Hospital, where the nurses are taught to syringe very gently. An irritable child or older delirious patient may resist the treatment, and so put undue stress on the heart or exhaust himself; or the fluid may be swallowed or dyspnœa induced or increased. Thorough swabbing every two or four hours during the day is then substituted. The gargling solution of peroxide of hydrogen (see above) may be prescribed for this purpose, or—

Acid. Carbolic. Liq. ♏ iii
Glycerin. Borax. ʒ i
Aq. ad. ℥ ss

Solut. Hydrarg. Perchlor. (1 in 4000).

If swabbing is barred for the same reasons as syringing, the medium containing formalin or carbolic acid may be sprayed on the throat instead at like intervals. Subacute or chronic tonsillitis, especially a sequel of *Scarlet Fever*, may also be treated by swabbing or spraying with one of these media or a marked astringent:

℞ Glycerin. Alum. ♏ xxx
Aq. ad. ℥ ss

Indolent, enlarged tonsils ought to be removed. Destructive ulceration, which may involve the palate and is a danger in septic *Scarlet Fever*, requires the same treatment as noma of the mouth (par. 1). If chlorate of potash is prescribed locally for the affections included in this and the previous paragraph, it should not be continued too long, as it is itself an irritant.

3. **The Nose.**—Acute rhinitis, besides being present in a slight or marked form in nasal *Diphtheria* and frequently in septic *Scarlet Fever*, is, in its milder catarrhal phase, specific to *Measles* and *Whooping Cough.* The objects of treatment are to get rid of the infective matter, to render breathing more easy, and to discourage sepsis. The nose is never syringed, as such treatment may induce otitis media, and it is questionable if even gentle

douching is safe. The best application is a very strong, coarse spray, two-hourly during the day at first and less often as the affection subsides. When there is much ulceration and foul discharge peroxide of hydrogen is one of the best agents to employ; otherwise nothing is better than formalin (see above). Chronic rhinitis is one of the most troublesome and obstinate affections in hospital practice, chiefly seen in children after *Scarlet Fever*, and not rarely after *Diphtheria*. Local treatment improves most cases, but although the discharge is reduced, congestion and swelling, with or without slight ulceration, are apt to persist, and further progress is then slow. As a rule, the writer begins treatment with a spray of formalin or peroxide of hydrogen. When response ceases, it is replaced by the following—

℞ Cupri. Sulph. gr. ii
Aq. ad. ℥ ss

Should this fail in effect, either from the start or after a time, an ointment is substituted—

℞ Ichthyol. gr. ii
Vaselin. ℥ ss.

This is inserted as far up the nostrils as possible with a cotton-wool swab made on the end of an eyed probe. Even so weak a preparation is at times too irritant; on the other hand, its strength may have to be increased, and in some cases the curative effect is remarkable. Vaccines may be used.

With the cessation of discharge under any treatment, zinc ointment is used if the mucous membrane remains congested, and, finally, boracic ointment or vaseline. Children may have to wear check-splints to prevent picking of the nostrils. Epistaxis is rather common in *Typhoid Fever* and may be due to vascular stress in *Whooping Cough*. It may then be stopped by spraying a little adrenalin into the nostrils. Again, it may depend on ulcerative rhinitis. In such cases, and when it is a sign of toxic changes in the vessels or, generally, is difficult to control, the nasal passages may have to be plugged via the nostrils with strips of lint smeared with boracic ointment. Its arrest is important in severe fever.

4. **The Ear.**—Otitis media is a characteristic complication of *Scarlet Fever*, fairly common in *Diphtheria*, less so in *Measles* and *Typhoid Fever*, and rare in *Mumps* and *Rubella*. In the early, painful stage, the meatus is syringed with warm boracic lotion every four hours and two minims of tincture of opium, mixed with three minims of olive oil, dropped into it from a warm spoon. A pad of wool, heated at the fire, is applied over the ear. When perforation threatens, myringotomy should be performed, but requires an expert, particularly if the patient be a young child. Syringing is continued after a discharge sets in, and in this stage, urotropin (4 gr. in water four times a day for a child) may bring rapid improvement. When infection spreads to the antrum, an incision is made to the bone to avert mastoidectomy, or at least to postpone it if possible if the patient is not yet convalescent from the primary fever. But if, as is the issue in a minority of cases, relief does not follow, and general disturbance referable to the local lesion is sustained, this or the radical operation is called for. Meningitis, thrombosis of the transverse sinus and cerebral or cerebellar abscess, are rare developments, for which the cranium is opened. Chronic otitis, usually ensuing on acute infection, ranks with rhinitis in the frequency with which it resists treatment and detains patients in hospital. The writer relies mainly on absolute alcohol to cure such cases. Success depends largely on the alcohol reaching the middle ear in quantity, and doing so undiluted. Hence, the ear is first syringed out with 10 per cent. peroxide of hydrogen solution to loosen and bring away crusts and clear out the discharge. With the ear dependent, the solution is then thoroughly dried out of the ear with pointed spools of absorbent wool. The alcohol is dropped into the meatus from a warm spoon and the tragus pressed very gently several times to aid its passage beyond the drum. The patient lies with the ear uppermost for five minutes, after which the alcohol is allowed to gravitate out. The application is repeated every night and morning, and in due course a full week's rest from all treatment is given to ascertain if the discharge, having become scanty, will stop. Vaccine treatment may be used.

5. **The Eye.**—Mild conjunctivitis, such as is usual in *Measles* and may complicate *Scarlet Fever*, etc., nearly always subsides quickly when a four-hourly moist boracic dressing is applied without pressure over the orbit. The same affection, in a more intense form, is specially frequent in *Smallpox*, and is treated through the acute stage by washing out the sac, at least every four hours while the patient is awake, with a mild antiseptic solution such as boracic lotion. The lotion is squeezed out of a piece of aseptic gauze. The lids are prevented from adhering by an ointment of boracic acid and vaseline (1 in 40). If conjunctivitis in any of the fevers becomes purulent, nitrate of silver solution (10–15 gr. to the ounce) should be painted on the inner surface of the lids every twenty-four or forty-eight hours until retrogression is assured. In subacute or chronic inflammation which does not yield rapidly to boracic dressings, it is advisable to dispense with drops, and to apply the same solution (5–10 gr. to the ounce). Corneal ulcer, occurring in *Smallpox*, is an

indication for the instillation of atropine (4 gr. to the ounce) unless the lesion is not only peripheral but is tending to perforate. The conjunctival sac may require constant cleansing. In keratitis, atropine is instilled and warm boracic fomentations applied.

6. **Glandular Structures.**—Adenitis, centred behind the angles of the lower jaw and showing in degree a fairly regular relation to the severity of the local lesion, is common in *Diphtheria* and *Scarlet Fever* and occasional in *Measles*. In the latter two diseases, boracic fomentations are applied, in the first, cotton-wool. In all, if there is much pain, the skin may also be painted with glycerine of belladonna. Abscess (very rare in *Diphtheria*) is opened by a small incision in line with the jaw, drained with a tube, and syringed out at each time of dressing. In chronic adenitis, primary or as a sequel to the acute form, the skin may be painted with iodine and syrup of iodide of iron prescribed. Given suitable conditions, much time should be spent in the open air. Necrotic subcutaneous cellulitis is a dangerous complication of the above fevers, although rare in Measles. The overlying skin is incised at several points when breaking down has commenced, and the tract well irrigated with one of the emulsifying germicides (1 in 40) every four hours. Boracic fomentations are applied early and continued while the skin and contiguous tissues are sloughing. Open-air nursing seems to favour recovery when the lesion is not too extensive, but the case-fatality is very high. The parotitis and other glandular lesions of *Mumps*, including orchitis, are treated with boracic or belladonna fomentations; the septic parotitis complicating *Smallpox*, *Typhoid Fever* and *Typhus* with the former, plus an incision if abscess occurs. According to Tirard, ichthyol and lanoline (equal parts) is an excellent dressing in *Mumps*. Chronic enlargement of the bronchial glands is one of the sequels of *Measles* and *Whooping Cough*. Treatment: Syrup of the iodide of iron, a liberal diet and open-air conditions.

7. **The Intestine.**—Febrile disturbance of this tract is accentuated by the ulcers of *Typhoid Fever*, but is considered as a general question later on, as the ulceration is probably unaffected by drugs. Two accidents due to it, however, require prompt treatment.

(A) *Hæmorrhage.*—The care taken in moving cases of Typhoid Fever is increased when blood shows in the motions. More or less continuous loss of blood, referable to oozing, is generally treated with turpentine: 20 minims every four hours. It is given in capsules, or a drachm of it is placed in a bottle with two ounces of milk and one-half of the white of an egg, and this emulsion slightly sweetened; the bottle is well shaken when a dose is administered. At intervals, especially if there is much diarrhœa, an opiate enema may be ordered: Tinct. Opii 20 minims in $1\frac{1}{2}$ oz. of starch mucilage. The diet of milk may be iced and reduced by half for a time. To still the heart, control restlessness, lessen peristalsis and protect from shock, the writer gives morphia ($\frac{1}{6}$ gr.) at once in the more sudden form of hæmorrhage if it is at all severe. Over the abdomen are placed small pieces of ice on a single layer of lint with its four edges pinned round rolls of cotton-wool which take up the water as the ice melts. Any trickle from the rolls is kept off the flanks by squares of batiste or jaconette, the upper edges of which are secured under the lint. The patient's lower limbs are kept warm by an extra blanket and a hot-water bottle. Food may be stopped for twelve to twenty-four hours, the patient merely receiving sips of water; on the following day, iced whey may be temporarily substituted for milk. Up to a certain point, a drift towards heart-failure is not counteracted as clotting is desired, but when syncope becomes the immediate issue, stimulating measures cannot be avoided. The patient is covered with relays of warmed blankets, if necessary, the foot of the bed raised, and salt solution (one to two pints, or even more) injected either subcutaneously or by venous puncture. Alcohol, camphor, strychnine and oxygen may also be employed.

(B) *Perforation*, apart from diagnosis and laparotomy within twenty-four hours, is practically always fatal. Morphia should be withheld until the question of an operation is decided. The details of diagnosis need not be discussed here, but it may be noted that pain, although often slight, is the most valuable sign, since it calls attention to the possibility that perforation has occurred. The other early and most reliable indications are quickened breathing and shrinking or disappearance of the hepatic dulness. The last sign is generally undervalued. Its significance depends largely on a daily examination of the area in cases likely to perforate and an hourly one from the time perforation is suspected. The main surgical points are that ether should be given by the open method; that the operation should be rapidly performed; that the peritoneal cavity should be cleansed by swabbing, and not washed out with saline solution unless peritonitis is already extensive; that gauze wick should be used for drainage in early cases, as against a tube for those in which the douche is employed; that the gauze should be removed in thirty-six hours as adhesions form; and that a saline infusion (one to three pints) should be given immediately after the operation and again in twelve hours. The patient having had salt solution, food can be discontinued for eight hours and then half an ounce of peptonised

whey given every half-hour for twelve hours. The whey is gradually increased to five ounces two-hourly, on the second and third days; then mixed with milk, which soon replaces it entirely. The recovery rate is said to be about 1 in 3, but many fatal cases are probably not recorded. In *peritonitis without perforation*, the writer keeps the patient free from definite pain by injections of morphia (say, $\frac{1}{6}$ gr. every twelve hours or less often) so long as tympanites is not developing. Hot fomentations or turpentine stupes are applied to any specially tender area.

8. **The Heart and Blood-Vessels.**—(A) In the writer's experience, no treatment affects favourably the purpuric lesions which mark the grave hæmorrhagic type of certain fevers (e.g. *Diphtheria, Smallpox*). (B) The myocarditic changes which are a factor in febrile heart-failure and occur in an extreme degree in some cases of *Diphtheria*, *Scarlet Fever* and *Typhoid Fever* are covered as to treatment by Part VI. of this section. (C) Endocarditis, while less rare in *Scarlet Fever* than other acute infections here considered (*Diphtheria, Measles, Mumps, Smallpox, Typhoid Fever, Typhus*) is by no means common in that disease despite the frequency of murmurs. The so-called simple form grades into the still rarer ulcerative type which is hardly ever frankly pyæmic. (D) Phlebitis, most often affecting the femoral region, is a frequent late complication of *Typhoid Fever*. The limb is raised on a pillow and bandaged from the foot with a domette roller; it should be kept still until the acute phase is past, although pyæmic infection is excessively rare. If there is pain, belladonna fomentations are used. The patient may, owing to continued œdema, have to wear the bandage for some weeks or even months after getting up, but in nearly all cases it ultimately subsides.

9. **The Respiratory Tract.**—See also article on treatment of the nasal passages.

A. The *Larynx.*—(*a*) Laryngitis is often present in early *Measles;* less frequently during its full development or decline. It occurs sometimes in *Whooping Cough*, may complicate septic *Scarlet Fever*, and is common in confluent *Smallpox*. The patient is placed in steam or uses a steam-inhaler if there is obstruction. In rare instances tracheotomy is required in the last two fevers for severe stenosis. The same is true of *Measles*, but here a further issue arises: as time passes in the incidence of croup, there is a greater chance that it is diphtherial, and the rule in all late cases is to give antitoxin without waiting for the bacteriological examination. The ulceration peculiar to *Typhoid Fever* may be present without symptoms, and very rarely indeed calls for surgical relief. In severe fever generally, slight but persistent obstruction may be an indication for operation. (*b*) The treatment of laryngeal *Diphtheria* has been placed on a new footing by the improved prognosis due to the success of antitoxin. Early cases are placed in steam, and oxygen may also be administered, especially at night. In this way, with antitoxin treatment, some patients are saved from operation. The need for the latter is mainly judged in young children by the degree of thoracic recession. Owing to the greater rigidity of the costal arch at and after the age of six, cyanosis and the state of the pulse gain relatively in importance. Rapid tracheotomy with a small incision is practised in hospital. The inexperienced, however, will find the ordinary operation easier, and should, if there is no time to follow it in detail, begin with the full-sized incision. Opening the trachea, as compared with intubation, is suitable for all cases, whereas the latter operation is contra-indicated when there is much naso-pharyngeal obstruction, faucial inflammation is of the ulcerous type, the patient has or has recently had Measles, or immediate asphyxia threatens. Also tracheotomy is not so difficult in the absence of special experience and offers the nurse a better chance of postponing fatal suffocation if acute obstruction returns and the medical attendant is not within call. It alone should be used in private practice. Intubation, again, gives less trouble than tracheotomy as regards preparation, the actual operation, and, especially, the subsequent nursing; is justified at an earlier and therefore more favourable stage of stenosis; and has a lower death-rate, probably under 30 per cent. at the present time. Patients should be nasally fed with peptonised milk for at least a fortnight if a tracheal tube is worn so long, and always while a laryngeal tube is in place. The writer strongly advocates the use of steam in all cases of tracheotomy, as, even with extensive broncho-pneumonia, death after the operation is in most instances directly due to gradual obstruction of the lower trachea and adjacent bronchi by inspissated discharge, and its development cannot be foreseen. The nursing of tracheotomy cases should be on strict aseptic lines.

B. *The Lower Respiratory Passages.*—The treatment of *bronchitis*, as regularly present in *Measles*, *Whooping Cough* and severe *Smallpox*, very consistently in *Typhoid Fever*, and incidentally in septic *Scarlet Fever* and *Typhus*, does not call for comment except in relation to the two first-named diseases, in which the occurrence of lobular pneumonia, especially among young children, is the chief clinical fact. (*a*) From the onset of *Measles* the patient is kept strictly in bed and should wear a woollen undervest. The head of the bed being screened to keep off draughts, there should be very free ventilation,

and, if compatible with it, an air-temperature of 65° F. In the early, dry stage of the catarrh, a good all-round prescription is—

℞ Vin. Antimonial. ♏ ii
Spirit. Æth. Nit. ♏ v
Liq. Ammon. Acet. ♏ xx
Aq. Camph. ad. ʒ ii

four-hourly for a young child. When this phase passes—

℞ Vin. Ipecac. ♏ v
Syrup. Scill. ♏ viii
Glycerin. ♏ v
Aq. ad. ʒ ii

also four-hourly. If bronchitis becomes marked, a steam-kettle is required; if dangerously suffocative, oxygen should be given. Should older children develop the capillary form, with glutinous secretion—

℞ Ammon. Carb. gr. ii
Ammon. Chlorid. gr. ii
Tinct. Seneg. ♏ iv
Syrup. Tolu. ♏ xxx
Aq. ad. ʒ ii

every four hours. The patient gets up when all signs of bronchial trouble have disappeared, and when the weather is fitting should be much in the open for some weeks after convalescence; he should also be well fed and not too thinly clad. Lobular pneumonia is, as a rule, a direct outcome of the acute bronchitis, but sometimes sets in during convalescence. (*b*) Treatment of the initial catarrh of *Whooping Cough* is on the same lines, but the danger of early lobular pneumonia is less as it is more specially a complication of the ensuing spasmodic stage. The spasms, though nervous in origin, are related to the severity of the enduring catarrh, each, doubtless, tending to maintain the other, a fact implying that treatment should be directed against both. At the outset, as in *Measles*, the freest ventilation should be secured, and its continuance is important in cases severe enough to be kept in bed during the spasmodic stage; secondarily, a temperature of 65° F. is desirable. In warm weather open-air treatment is best. Frequent vomiting due to the paroxysms may seriously affect the nutrition, and early in such cases the patients should be given some predigested food (*e. g.* Benger's) immediately after the seizures. Response to medicinal treatment on the part of the paroxysms is variable; a drug which benefits one case may fail in another. The prescription containing ipecacuanha and squill (see above) may be continued after the whoop sets in; to it a bromide or belladonna may be added, or they may be prescribed alone—

℞ Sod. Bromid. gr. ii
Tinct. Bellad. ♏ ii
Glycerin. ♏ viii
Aq. ad. ʒ ii

four-hourly for a child aged four. The pushing of belladonna is widely favoured—

℞ Tinct. Bellad. ♏ iii
Spir. Chloroform. ♏ iv
Aq. ad. ʒ ii

every four hours, the tincture to be increased with each dose until the pupils are dilating and thereafter continued with caution. Bromoform relieves some severe cases. Owing to its pungency it should be freely diluted. As a poison which tends to sink in mixtures, it is best prescribed in separate doses: 4 minims with 10 minims of rectified spirit in an ounce of water four-hourly at the age of four. Antipyrine has many advocates: 1 gr. cautiously increased to 2 gr. thrice daily for a child of four. Oxygen is used in very severe paroxysms; also a little chloroform by inhalation. When the spasmodic stage is unduly prolonged—

℞ Quinin. Sulph. gr. ii
Acid. Hydrobrom. Dil. ♏ v
Syrup. Aurant. ♏ xv
Aq. ad. ʒ ii

three times a day for a child of four. The removal of enlarged tonsils and adenoids may also be indicated. Exposure to cold air may favour persistence, which is unfortunate in view of the need for free ventilation. Most children, being up in the paroxysmal stage after a time, can be out of doors in the middle of the day if there is a convenient garden and the air is not too cold or dust-laden. On recovery, the general health should receive the same attention as after an attack of Measles.

C. *The Lungs and Pleura.*—(*a*) Lobular pneumonia may develop in septic *Scarlet Fever.* If there is coughing when fluids are taken, the patient is, unless rhinitis prevents, fed with the nasal tube. For broncho-pneumonia itself, as also when it complicates laryngeal *Diphtheria* and severe *Smallpox*, ammonium carbonate (5 gr. for an adult, 1–2 gr. for a child) may be prescribed four-hourly in milk. In the first of these diseases it is useful when tough discharge is obstructing the lower trachea and main bronchi after tracheotomy. Multiple cases of lobular pneumonia in hospital should be nursed as units, since there is reason to believe that the pneumonic affection may spread from one to another. In all cases of lobular pneumonia the patient's position in bed should be frequently changed. As the cause of so many deaths from *Measles* and *Whooping Cough*, it requires special consideration, and

here open-air treatment is entitled to the first place. Discrimination is, however, necessary as regards the exposure of individual patients to cold air. Particularly in *Whooping Cough*, cases not doing well in the open may improve on removal to a warmed room or ward. Through the warmer months of the year nearly all cases can be treated continuously in the open air, whereas when it is chilly at night some are better within doors at this time. The writer does not favour out-door treatment in winter. If cases are kept indoors owing to a low air-temperature or because there are no facilities for outside treatment, very free ventilation is essential. All patients should wear a cotton-wool jacket. When the bronchitic element is marked, ammonium carbonate is of great service in many cases; the chloride may be combined with it (see B). Stimulation is begun before weakness of the heart has become very marked; alcohol may be given first and continued if supplementary agents have to be employed. For high temperature, patients are tepid-sponged. A warm bath with a cold douche to cause deep breathing and so more fully aerate the lungs in cyanotic cases, is recommended by some authorities; the method is more suited to hospital than private practice. Oxygen should be administered when cyanosis begins to tell on the heart. A liberal and nutritious diet, suitable to the individual case, is important, owing to the tendency to asthenia and emaciation and the long period of fever. (*b*) The common liability to *hypostatic congestion* in *Typhoid Fever* and *Typhus* is counteracted by placing a pillow partly under the body on each side alternately in order to raise the level. The congestion may deepen to a low form of pneumonia in which cardiac stimulation, open-air treatment, and oxygen from the onset of cyanosis are chiefly to be relied on to save life. (*c*) *Lobar pneumonia* is met with now and then in *Measles*, and occasionally also in *Typhoid Fever;* it is rare in *Diphtheria*, *Scarlet Fever* and *Whooping Cough*. (*d*) *Pleurisy* and *empyema* are exceptional or rare complications of certain fevers.

10. **The Skin.**—(A) All but the gravest cases of fever are washed from head to foot between blankets every night and morning. In *Chickenpox*, *Smallpox* and *Typhoid Fever* an emulsifying disinfectant may be added to the water (1 in 100). (B) The irritation of the *rash* in *Chickenpox*, *Smallpox*, etc., is partly allayed by sponging the skin with 1 in 40 carbolic lotion. Salol largely controls it in the second disease. In both, to prevent laceration by scratching, the hands may be loosely enveloped in lint bags, tied about the wrist with tape. Even then children may have to wear check-splints to save the face from friction. Owing to the presence of variolar pocks on the arms, the splints are at times applied over lint spread with vaseline. Patients at all ages should have their nails closely trimmed. A warm bath (96° F.), besides favourably influencing the febrile disturbance of *Smallpox* in selected cases, is soothing to the skin; one may be given in the evening, or, as a recognised method of treating the disease, thrice daily or four-hourly. There are also good reports of the continuous bath. Iced compresses lessen pain caused in the hands and feet by the eruption. Even women's hair is cut short if the rash is profuse on the scalp. Maturation, so far as the writer's observations go, is not definably modified by any local application or by red light. To lessen pitting, however, Welch and Schamberg recommend the painting of the face once or twice a day with tincture of iodine if tolerated, as is usual, from the outset till about the tenth day of the rash. Rockhill, using 10 per cent. of iodine in glycerine, confirms their findings. Throughout an attack of Chickenpox, and in Smallpox when incrustation is established, if not sooner as mentioned above, patients should have a daily warm bath. If deep ulcers form in *Chickenpox*, open-air treatment should be adopted where possible, the patient well fed, and a tonic prescribed. (C) *Boils* and *abscesses* (*e. g.* in septic *Scarlet Fever*, *Smallpox*, *Typhoid Fever*) are fomented and incised. Widespread abscesses of the skin, perhaps metastatic, are a rare feature of septic *Scarlet Fever*, and require the same treatment. (D) Bedsore is generally a result of carelessness in the nursing of *Smallpox*, *Typhus* or *Typhoid Fever*, but may result from a previous skin affection or from boils or abscesses. The nurse sees that the bed under the patient is kept smooth, and moves him carefully to prevent friction. In Typhoid Fever he is regularly turned partly on one side and then the other, to vary the areas of pressure. The chief point, however, is to keep the back dry and to save it from the irritating effect of urine and fæces. Any evacuation is washed off at once with soap and water and the soap removed with pure water. The skin is then well dried, dabbled over with methylated spirit, and powdered with equal parts of zinc oxide and starch. If the skin becomes inflamed, it is the nurse's duty to report without delay. In such cases frequent diarrhœa and incontinence of urine are the usual cause; to render the skin relatively "water-proof" and improve its circulation, it is gently massaged with lanoline. The patient may be placed on a water-bed and pressure kept off the part by a ring-pad, which is also used when an ulcer forms. The latter, cleansed if necessary by first applying a charcoal poultice, is dressed with red lotion. (E) *Cutaneous sores in the acute stage of fevers and*

as sequels.—Apparently because of the desquamation, patients suffering from *Scarlet Fever* are specially liable to sores, and these may also form in any fever characterised by a local discharge, notably *Diphtheria.* The skin about the mouth, nostrils and ears is most often affected. Largely as a phase of prophylaxis, the fever nurse is expected to avert the formation of sores even when discharge is copious. When washing the patient, she is careful to cleanse the skin thoroughly and dry it well; where the discharge emerges, the adjacent skin is thickly smeared with lanoline. Children are apt to scratch themselves owing to the irritation and may so start sores or hinder healing. Their hands may then be muffled (par. B). In hospital, as a more effective method, check-splints are applied. These are slips of cardboard, lightly bandaged to the front of the elbows, and allow the patient to bend his arms slightly but not to touch the face. The treatment of actual sores is bound up with that of the lesions from which the discharges come, a question dealt with elsewhere in this article under various heads; in chronic cases it includes the use of vaccines. The sores are cleansed with a boracic fomentation and dressed with zinc ointment, copper sulphate solution, or, as a very useful all-round application, ammoniated mercury ointment mixed with as much vaseline.

11. **The Urinary Tract.** — (A) Albuminuria complicates most fevers at times, either in the acute stage, when it may be transient or persist in convalescence, or as a passing or chronic sequel. In *Diphtheria*, *Scarlet Fever* and *Typhoid Fever* it is frequent. When marked in the febrile stage, fluids are given very freely, and the loins poulticed if the urine becomes scanty. The patient wears a woollen nightdress and broad flannel belt. Abundant fresh air is needful; in summer, under proper conditions, the patient's bed may be placed out of doors. Liq. Ammon. Acet. (1 dr. four-hourly in milk or a mixture) may be prescribed from the outset, even in the severest cases, and Spirit. Æth. Nit. (15 m. for an adult) added if the decline is slow. A laxative should be given daily, or less often as required; severe purgation is, in the writer's opinion, undesirable. If, with a normal temperature, the albumen has not disappeared after ten days, and the patient's general condition is satisfactory, boiled fish can usually be included in the diet. In more chronic cases, fluids should be given in quantity, and perchloride of iron may be prescribed thrice daily. Protein food is restricted, but not unduly. Following four weeks of stationary albuminuria without fever, the patient can generally be allowed up, given that the amount of albumen is not large. In any event, it does not benefit chronic cases to keep them in bed indefinitely; marked improvement or recovery may quickly follow when they are permitted to go about. Fresh air seems to aid recovery; suitably clothed, such patients need not as a rule be kept within doors in warm, dry weather. Should the albumen persist for, say, two months, and particularly if there is only a trace, the effect of cantharides is worth trying: half a minim thrice daily, increased progressively to three or four minims within a fortnight. It should be discontinued, or the dose reduced, if the albumen increases. (B) *Nephritis,* uncommon or rare in other fevers, including *Chickenpox, Diphtheria, Smallpox, Typhoid Fever, Typhus* and *Whooping Cough,* is the most characteristic complication of *Scarlet Fever,* in which its incidence, with infrequent exceptions, is confined to the convalescent stage. The early treatment of its acute phase is the same as in albuminuria (see above). Firstly, however, to maintain the flow of urine is a more salient point, since uræmia lies ahead as the chief danger to life. Water is pushed and may be given by the rectum as well as orally. Large poultices are applied to the loins at once and continued until the decline is well advanced. Secondly, while it has been suggested that vomiting may be eliminative, and that it should not be too readily discouraged, it is the writer's practice to stop it as soon as possible. Thirdly, strong purgatives are commonly given and repeated. It is the writer's experience that harm may be done by pushing such treatment; at the same time, the bowels have to be kept open, and smart purgation serves an end in exceptional instances of extensive œdema or when this condition affects the lungs. Fourthly, sweating is induced, if need be by steam or hot-air baths, and here again the writer prefers the middle course to extreme treatment. Fifthly, the patient lies between blankets, wears a woollen nightdress and also a broad flannel belt when poulticing is stopped; exposure of the body to cold air is avoided. Uræmic symptoms make more urgent the necessity for keeping up the flow of urine: especially so, as most cases are not in actual danger for more than a few days, and what is almost a crisis usually follows: a marked increase in the output of urine and quick general improvement. Whiffs of chloroform will mitigate severe convulsions, during which the breathing may be freed by holding the jaw forward and securing the tongue with forceps, while a cork is kept between the teeth to prevent the latter from being bitten. Cyanosis due to convulsions may be a factor in heart-failure, and specially indicates the use of oxygen. No case, at any age, should be allowed to die without blood-letting as a last resource: from three to five ounces are taken from a child, up to fifteen

ounces from an adult. If, in the course of recovery, the nephritis eventually becomes more or less chronic, tincture of cantharides may be tried with the reservations already noted.

The other treatment recommended for prolonged albuminuria applies to persisting nephritis, but patients are kept longer in bed, especially in winter. When they are up, and for some time after the disappearance of blood and albumen from the urine, the question of exposure to cold, and therefore of clothing, remains important. (C) When cases of *cystitis* in *Typhoid Fever* resist urotropin, the bladder may be washed out once daily with boracic acid solution (20 gr. to the ounce). For chronic cases resisting this treatment a 2 per cent. solution of argyrol may be substituted. *Retention*, common in *Typhoid Fever* and *Typhus*, and not very rare in other acute infections, is favoured by the recumbent position. Children, unless too ill, should be seated in a warm hip-bath, which seldom fails to act; if the bath cannot be used, a large fomentation is applied over the lower part of the abdomen. Urotropin is given when the catheter has to be passed in Typhoid Fever. (D) *Vaginitis*, a rare complication of *Scarlet Fever*, etc., will usually yield quickly to a daily douche of argyrol (10 per cent.), replaced after four days by perchloride lotion (1 in 5000).

12. **The Nervous System.**—Early and adequate doses of antitoxin lessen the incidence of paralysis in *Diphtheria*, and its severity when it occurs. From the first symptom—usually a nasal voice—the patient is kept lying down. Nasal feeding is begun at once if a food-cough develops. Strychnine is generally prescribed; some give it in minimal doses (*e. g.* $\frac{1}{500}$ gr. every eight hours, hypodermically), while others push it within the safety limit. Neither statistically nor clinically has the writer been able to make sure that it modifies the course of the paralysis, and this statement also holds for galvanism, which is begun later. He is not in favour of allowing patients with mild and stationary paralysis to sit up in bed, since there is ample evidence that trivial forms of exertion may aggravate or prolong the affection. In the declining stage his patients do not sit up until the last sign of paralysis has disappeared. Involvement of the respiratory muscles is always grave. The bed is tipped up at the foot; oxygen may also be given for cyanosis and to relieve distress, but as a means of saving life it has proved disappointing. So-called paralysis of the heart, a late disturbance, sometimes associated with the peripheral affection in its severe form, and seen typically as a paroxysmal weakening of the circulation accompanied by other symptoms, is very dangerous and demands direct stimulation.

13. **Bones and Joints.**—(A) The *osteo-periostitis* of *Typhoid Fever* may or may not go on to suppuration, and is treated accordingly with fomentations or by incision, which suffice for most cases. (B) *Non-suppurative arthritis*, peculiarly frequent during the decline of *Scarlet Fever*, is treated like mild acute rheumatism. (C) Suppurative arthritis, a rare feature of septic *Scarlet Fever*, yields as a rule to incision and washing out with an antiseptic solution. Apart from associated general infection, the prognosis in cases so treated is on the whole remarkably good, both as regards survival and recovery of the joint.

V. The Treatment of Fever, chiefly in relation to Cardiac Weakness

Acute microbic intoxication is considered under this head in its graver phases. Therapeutically, its pyrexial element is brought into undue prominence by the term "fever"; the salient feature from this standpoint is not a rise in temperature, which may, indeed, be absent, but cardiac enfeeblement; when death results from fever *per se*, gradual heart-failure is nearly always the mode, and treatment is largely directed from the first against this drift towards syncope. It is not to be expected that medicinal measures will antagonise, as a whole, a form of poisoning so complex. Although they are often useful, dependence has largely to be placed on others which sustain resistance to infection, while extrinsic factors directly or indirectly depressant to the circulation are minimised if they cannot be obviated. As regards depressing factors, cardiac debility tends to increase despite all available means of treatment, and it is proportionately important to recognise that this weakness is readily and often quickly induced, whereas recovery of the lost ground is usually slow and may be impossible. Finally, even main indications cannot all be met in many critical cases, and life may then depend on a timely recognition of what is essential in treatment.

1. **Dieting.**—(A) Without referring in detail to experimental facts as to the relation between nutrition and resistance to infection or between the former and cardiac efficiency as observed clinically, it may be said that to give food proper in kind and sufficient in quantity is the first rule of treatment; that in dieting fever cases, digestive disturbance is more readily determined or aggravated than checked; and that, in respect of quantity, practice must often fall short of principle. As formal pudding, fish and meat diets do not figure in the treatment of marked fever, they may in their general application be dismissed with the statement that the first, or even the second, is commonly given in the acute stage of mild cases; that in

severe cases a pudding diet is usually begun when the decline is established; that fish is added in these cases early in convalescence; and that fish partly gives place to digestible forms of meat in three or four days. This course can be followed in *Scarlet Fever* without an increased incidence of nephritis. The gradation to a full diet in *Typhoid Fever* is carefully regulated. When decline is certain and the appetite returns, the patient can have cocoa, chocolate and weak tea to drink; also junket and Benger's food two or three days later, with egg-custard and milk-jelly for a change, and bread-crumb, light sponge-cake, bread-and-milk and milk puddings, in the course of the first week of convalescence. At the beginning of the next week, in the average case, boiled white fish may be allowed with a suitable vegetable in small quantity; in the following four days, boiled sweetbread and stewed tripe; at the end of the week, chicken, minced at first. *Milk diet.*—The drawbacks to cow's-milk as a complete diet need hardly be discussed here, nor need methods used to soften the curds, or make them less coherent or smaller, be described. Such treatment of milk is indicated when there is nausea, vomiting or diarrhœa, and always if undigested curd appears in the stools. For particular cases of gastric disturbance it may be advisable to skim the milk lightly. Lactose or glucose (1 oz. to the pint) is sometimes added to raise the carbohydrate content, but increased intestinal fermentation may result. If milk is given over a long period in *Typhoid Fever*, salt should be administered in it, or, as recommended by Ker, liberally in beef-tea. When a fever occurs in infancy, dieting has a special importance, as vomiting and diarrhœa are common at this time and frequently dangerous (*e. g.* in *Measles*). In the first six weeks of life, one part of milk and two of water are given to fever patients: total amount of the mixture for twenty-four hours, 18 oz.; in the second six weeks, equal parts: total amount, 24 oz.; in the next four months, one part of water and two of milk: total amount, 24 to 36 oz. The last dilution serves up to the age of one year, with an increase to 44 oz. Thereafter, with exceptions in the case of children just past infancy, one part of water may be added to five parts of milk at all ages, unless it is desired to use the milk as a vehicle of extra water. Young children receive 36 to 48 oz. of the actual milk; older ones 48 to 60 oz.; adolescents and adults, from 60 to 80 oz. Only for those suffering from inanition when first seen, taking insufficient milk, or showing a tendency to emaciation during a long attack of fever, need this diet be supplemented by raw egg, beef-tea, meat extract, cream, a standard proprietary food, etc., according to age, the state of digestion, and the presence or absence of idiosyncracy. *Milk substitutes.*—Occasionally milk, however treated, is rejected or ill-digested. In its place, Benger's food made with water and, possibly, a little cream, may then be given. (B) The experimental fact that the withholding of *water* reduces resistance to one infection is probably true for all. Besides this reason for giving an adequate amount in severe fever, there are others which point to the advisability of pushing it: notably, the tendency of the urine to become scanty. Milk, as regularly diluted (see above), provides the minimum quantity; more may therefore be added to it or ordered as a beverage (lemonade, imperial drink, orange water, apple water); the total for an adult suffering from one of the longer fevers (*Smallpox*, *Typhoid Fever*, *Typhus*) with oliguria reaches six pints. (C) *Methods of feeding.*—Milk diet is divided into two-hourly feeds during the day, and four-hourly ones at night, so that an adult receives respectively five ounces and ten ounces at a time. The intervals should be maintained unless the milk is peptonised. If the spasmodic vomiting of *Whooping Cough* is interfering with nutrition, the patient is fed immediately after the paroxysms with pre-digested milk and concentrated foods in small quantities. Because of distaste for food, pain on swallowing, tonsillar swelling, irritability, delirium, marked dyspnœa or coma, insufficient nourishment may be taken by the mouth, and the nasal tube—an instrument which probably saves many lives—is then generally used; eight ounces of peptonised milk are given every four hours to a child of four. Rhinitis, with obstruction or epistaxis, may prevent nasal feeding, and what is taken by the mouth may then be supplemented by suppositories, rectal injections, or both (see below).

2. The Prevention and Control of Vomiting.—The initial vomiting of *Diphtheria*, *Scarlet Fever*, etc., has rarely any prognostic significance, but that this is a leading issue in cases of late sickness is indicated by the fact that there is a loss of both food and water, rest is disturbed, and physical exhaustion is at times induced. Primarily, the cause has to be dealt with. When it is local the addition of a drachm or two of whisky or brandy to a nauseating drug or to food may act as an antemetic. Otherwise treatment is mainly dietetic. Milk may have to be altered or replaced by one of the temporary foods mentioned below. In the worst cases the stomach requires rest, and nourishment is administered *per rectum*. Peptonised milk, unboiled after preparation, is given every four or six hours to the amount of four or six ounces, according to the interval. If this is not retained, peptonised meat suppositories may be ordered every four or six hours with saline

enema or infusion (one pint) every morning and evening. If even iced water has been rejected by the stomach, an attempt should be made to give it again in twelve or twenty-four hours. When tolerated, the quantity is cautiously increased, and in due course the water is replaced by albumen water, peptonised whey or white wine whey. Raw meat juice and champagne may be tried; also small doses of a beef-tea or extract so prepared as to have some nutritive value—low at best. Where, in cases less grave, treatment can be begun with such foods, the necessity for progressing to a complete food should be constantly in view. Meanwhile, very dilute whisky or brandy may be included in the diet. "Late vomiting," as a strict term, is applied to the obstinate sickness which sets in very frequently in *Diphtheria*, and now and then in other fevers, when the heart has become markedly degenerated if not dilated. As the critical period approaches in the disease named, care should be taken not to start vomiting by the use of purgatives, other drugs or some change of diet; whether so determined or spontaneous in its onset, its arrest is one of the most difficult and vital problems in the treatment of Diphtheria. As a rule all measures fail, but Ker states that it may sometimes be checked by hypodermic injections of morphia and atropine. Coghlan recommends—

℞ Atropin. Sulphat. gr. $\frac{1}{100}$
Strychnin. Hydrochloride gr. $\frac{1}{100}$
Solut. Adrenalin. Chlorid. (1–1000) ♏ v
Aq. ♏ x

hypodermically every four hours. The author would exclude strychnine from this prescription. Given alone, it is ineffective if not harmful. The view that atropin may act beneficially is strengthened by Dr. G. C. Garratt's observations in a few cases treated on somewhat original lines. He advises the early administration of belladonna by mouth. If vomiting continues, nothing is to be swallowed, but the patient fed every 4 hours by enemata, each containing 20 to 30 minims of tinct. belladonnæ. Twice in 24 hours 20 gr. of potassium or sodium bromide are to be added. These doses are for a child of 3 or 4. An hour after the bromide the patient is wrapped in a large towel. The operator spreads a mackintosh on his knees and takes the child's head between them while the nurse holds the body and legs. The mouth being sufficiently open, a good-sized œsophageal silk-gum tube is passed rapidly. When the resulting disturbance has subsided, water at 115° F. is poured in. At first the water is rejected, but the stomach becomes more tolerant as it fills. Enough must be given—10 to 12 oz. The tube is withdrawn quickly but cautiously and the patient taken to bed with the utmost gentleness after a due interval. Rectal feeding is continued and, if all goes well, the bromide first reduced gradually and then the belladonna. The tube feeding is repeated every 12 hours and some bland food leaving no curd substituted for the water, *e.g.* somatose. The writer has seemingly saved an occasional case by giving oxygen for ten minutes every hour. Oxygen and infused saline solution are always worth trying in persistent febrile vomiting, with poulticing of the loins if a uræmic element is diagnosed or suspected.

3. The Prevention and Control of Diarrhœa.—The reasons for treatment are the same as in vomiting, danger being greatest when young children are affected. A mild purge to clear the intestine, and, afterwards, a laxative to ensure a daily motion if there is constipation, are routine measures in fever cases, but the writer regards drastic purgation, especially after the initial stage, as rarely advisable. Dieting may mitigate or stop diarrhœa (see pars. 1 and 2). Beef-tea or peptonised milk may cause it, and have to be withdrawn. In the putrefactive diarrhœa of fevers as a whole, antiseptics are more serviceable than astringents. Combining the qualities of both, and first in all-round value, is bismuth salicylate: 4 gr. in mucilage of acacia, 20 minims with water to 1 drachm for a child of four, thrice daily or every four hours; or 2 gr. with an equal dose of salol, may be prescribed in the same vehicle. If such signs as pallor, pinching of the face and a small, weak pulse, show that the loss of water is prejudicing the circulation, salt solution should be infused; as a method of giving water, infusion also remains when it is rejected by mouth and rectum, as may be the case in *Measles* and toxic *Scarlet Fever* accompanied by vomiting and diarrhœa, or when there is vomiting and rectal intolerance without diarrhœa. In *Typhoid Fever*, chlorine water has a long-standing reputation in the control of severe diarrhœa; allowance being made for its slow action, it is a useful preparation: the dose is ½ to 1 oz. every four hours, and may contain 1 to 2 gr. of quinine. If a quicker result is desired or the chlorine does not act in four days, salol (10 gr. finely powdered, every four hours) or beta-naphthol (10 gr. thrice daily in cachet) may prove effective.[1] Should such agents fail: tincture of opium, 5–20 minims, according to age, may be given as an enema in 1 to 2 oz. of starch mucilage, not to be repeated within twelve hours. Statistics

[1] Tincture of iodine (3–4 min. thrice daily) has been praised in the treatment of *Typhoid Fever*, but as it is also recommended for *Typhus*, its effect may be partly general, since the febrile disturbance of the two diseases present common features.

show that there is a better average chance of recovery when patients are constipated in this disease, for which the writer never uses even a laxative. Constipation is relieved by enemata every day or second day.

4. **The Control of Abdominal Distension.**—Generally, distension is taken to signify some modification of diet, and is thus controlled indirectly. It may, however, threaten to embarrass the circulation and breathing (*e. g.* in *Typhoid Fever* and the broncho-pneumonia of *Measles* and *Whooping Cough*), and has then to be treated more promptly. Turpentine may be ordered by the mouth : 5–15 minims every four hours, in keeping with the patient's age and the condition of the kidneys; the latter may prevent its use, and an intestinal antiseptic (see above) have to be substituted. From two drachms to one ounce of turpentine may also be given in a pint of starch mucilage as an enema and ice applied to the abdomen.

5. **Ventilation.**—That an abundant supply of fresh air is beneficial in febrile disturbance, and may lessen the chance of heart-failure by sustaining vitality is, in the writer's opinion, proved by clinical observation. This result is most obvious in the open-air treatment of *Typhus ;* such treatment has been extensively employed for Typhus alone, but the writer believes that its common adoption for selected cases of many other acute infections is only a matter of time. Its utility in local respiratory affections is beyond question. Unfortunately, as a secluded verandah is necessary in a private house, it is rarely feasible under home conditions, but should in most cases be approached as nearly as circumstances allow. Cross ventilation should be secured if possible, and the windows kept wide open except in cold weather, when inlets can be provided by opening them at the top and closing the lower sashes on ventilating boards, while a fire is used for the removal of foul air *via* the chimney.

6. **The Avoidance of Chill.**—As indicated by coldness of the surface of the body, and especially of the extremities, undue chilling may have an adverse influence on the circulation when it is already weakened by fever; moreover, such added depression tends to persist, for example, in *Diphtheria.* This, however, is rarely an obstacle to free ventilation; for, although in the above disease, and in *Measles* and *Whooping Cough*, a temperature of 64° F. is best, the breathing of warmed air must be considered a minor question in comparison with the proper clothing and covering of the patient and the use of hot bottles when necessary. If, through careless nursing, a severe case of fever becomes chilled, warmed blankets should be tucked round the patient, hot bottles placed near the feet, and stimulation pushed.

7. **The Relief of Forced Breathing.**—The reference here is not to the gross occlusion of the air passages characterising diphtherial croup, but to its presence in a minor degree as a result of nasal and faucial obstruction or slight œdema or ulceration of the larynx, mostly met with as complications of septic *Scarlet Fever.* Frequently, the continued effort affects the weakened heart, and may mainly determine the unfavourable course of given cases. Timely tracheotomy may then save life.

8. **Æration of the Blood.**—Even when slight, cyanosis is not a sign which can be safely neglected if the heart is weakening. In some instances, swelling and the collection of discharge in the naso-pharynx may be the cause, in others, laryngeal obstruction, bronchitis, lobular pneumonia, hypostatic congestion, lobar pneumonia. Local treatment of the nose and throat, or feeding by the mouth, may have to be discontinued because they cause respiratory distress or make children resist or hold their breath. Whatever other treatment is adopted under the heads cited, oxygen inhalation is beneficial. When the cyanosis is associated with hypostatic congestion or lobular or lobar pneumonia, it is an indication that the heart should be stimulated.

9. **The Maintenance of Renal Excretion.**—As bearing on treatment, it is significant that febrile urine is abnormally toxic, and that a rough proportion exists between the severity of the typhoid state as observed in diseases with a long febrile stage (septic *Scarlet Fever*, *Typhoid Fever*, *Typhus*, etc.), and the quantity of urine passed. In such cases, and also in *Diphtheria*, the urine should be measured and charted every twenty-four hours. The early and continued administration of water in addition to that contained in milk, is the first step in their treatment. In the fevers generally, and specially in Diphtheria, as the result of a specific process, the lessened output of urine results, in part at least, from loss of vascular tonicity, aided by cardiac weakness in many cases. If the deficiency becomes a danger, the methods of increasing the urine in scarlatinal nephritis apply, but improvement of the circulation may be the main consideration. The good effect of hydrotherapeutic treatment in suitable cases (par. 10) is largely attributable to constriction of the vessels and a consequent increase in the urine excreted.

10. **The Control of Pyrexia.**—The theory that pyrexia is merely an expression of resistance to infection does not negative the treatment of a high sustained temperature as far as may be safely possible, since the relation between it and some nervous forms of febrile disturbance is such that its reduction is often desirable, and it seems

directly to affect the heart even when it does not amount to hyperpyrexia. However, the effect obtained, particularly in improvement of the circulation as against its depression, should decide the question of further treatment, continued or occasional. The very young, those past middle age, and some who have heart disease, are not good subjects for active or prolonged hydrotherapy, while bathing is contra-indicated in *Typhoid Fever* if there is hæmorrhage or limited peritonitis, or, obviously, perforation is suspected or has been diagnosed. It is better, again, when drugs are prescribed for their antipyretic effect, to reserve them for conditions in which a temporary fall is desired or hydrotherapy has to be supplemented; they are neither safe nor reliable agents for producing more than a passing modification of the temperature.

(A) *Sustained Treatment.*—(*a*) The *continuous bath* is mainly used for *Typhoid Fever* with a high average temperature, and is life-saving, but should not be attempted without special apparatus. Patients are immersed for days at a time, the temperature of the water varying, inversely with that of the patient, between 90° and 98° F. This bath is also beneficial in severe *Smallpox.* (*b*) The *continuous pack* serves for similar cases of *Typhoid Fever* and when hyperpyrexia is feared. The patient wears warm stockings to the knee, and over them a blanket is tucked. From knee to neck, with the arms outside and bandaged in cotton-wool, he is closely covered with a wet sheet taken from water at 90° F. More water at the same temperature is dribbled on to the sheet from a sponge as evaporation occurs. If there is depression, the added water may be at 98° F., but in any case the treatment has often to be stopped owing to the effect on the heart. (*c*) *Ice.*—High temperature, more particularly when associated with cerebral excitement, as is frequent in *Typhus* and occasional in *Typhoid Fever*, may, after the hair has been cut very short, be treated by suspending an ice-bag over the patient so that it lies lightly against the head, or by applying an ice-cap or, preferably, an aluminium cap of Leiter's tubing served with iced water. Ice-bags may be placed along the upper part of the spine and in the axillæ and groins when the temperature keeps in the neighbourhood of 105° F. As a matter of comfort rather than to reduce temperature, patients may be covered with an ice cradle in warm weather. (*d*) *Diaphoretics* are largely prescribed for the discomfort associated with a high temperature and dry skin, notably when there is also a dry catarrh of the respiratory tract (*e. g.* in the first stage of *Measles* and *Whooping Cough*); but, although even hyperpyrexia may occur when the skin is moist, it seems that sweating induced by drugs may aid the imperfect control of pyrexia by the nervous system. The latter effect is most apparent in the case of young children—

℞ Pot. Cit. gr. v
Spir. Æth. Nitros. ♏ v
Liq. Ammon. Acet. ʒ i

for a child of four; hourly for four doses, then every four hours.

(B) *Periodical and Incidental Treatment.* (*a*) The *gradual bath* is the most effective agent in treating hyperpyrexia, one of the gravest developments of *Typhoid Fever*, etc. When the temperature is 106° F. or more, what chance there may be of saving life usually depends on an immediate and marked reduction. If, therefore, the danger has not been foreseen and a bath kept ready, during its preparation the patient should be wrapped in a sheet saturated with cold water. At this time, or whenever he is in the bath, he should receive ten and five grains respectively of quinine and phenacetin with an ounce of brandy or whisky, not too dilute. The temperature of the bath is at first 100° F., and is lowered by pouring in cold or iced water at the foot, while the warmer water is bailed out at the other end. Shivering and mental distress are ignored, but the pulse has to be frequently noted, as collapse is possible. On removal from the bath when the rectal temperature has dropped to 101° F. or, as the limit of the treatment, in half-an-hour, the patient is given half an ounce of whisky or brandy and dried with friction. Children are least subject to hyperpyrexia, and can be given a cold or tepid pack, with quinine and alcohol in doses suitable to their age. (*b*) The *repeated bath* has its greatest vogue in the treatment of severe *Typhoid Fever*, given either every four hours or when the temperature reaches a stated level, such as 103° F. The cold bath (65° F.) is now less favoured than the warm one (80° F.). Evidence is abundant that these baths reduce the average mortality of the disease. (*c*) *Tepid* and *cold packs* replace graduated, tepid and cold baths when the latter are contra-indicated or cannot be provided. For a tepid pack the temperature of the water is 85° F., for a cold pack, 65° F. or less; iced water may be used in the hyperpyrexia of adults. They are given, in the same way as the continuous pack (see above), for thirty minutes, an hour, or longer. (*d*) *Hot sponging*, having as its object the dilatation of the superficial vessels to cool the blood in quantity, is employed when the temperature rises towards 105° F., and the circulation is so depressed that cold or tepid applications do not induce a favourable re-action. Its success and safety depend on the

use of water as hot as the patient can bear with comfort, and its completion in four minutes. Except as regards the lower extremities, the patient as a rule is afterwards only covered with a sheet for half-an-hour. The fall in temperature is apt to be transient. The great flexures are not sponged. (*e*) *Cold* or *tepid sponging* is the favourite method of reducing temperature in *Typhoid Fever*, etc. Cases may be sponged for twenty minutes at set intervals or when 103° F. or some other point is touched. The sponge, or, in hospital, lint square, is applied with special thoroughness to the great flexures and along the spine. In cold sponging, the extremities, from the knees and elbows, are excluded.

11. **The Securing of Rest and Sleep.**—The improvement frequently observed in the pulse of grave fever cases after sound sleep is the only point which need be mentioned to define the bearing of this issue on heart-failure. To obtain a quiet sick-room, other requirements may have to be sacrificed in a noisy house or neighbourhood. The lighting of the room is another factor; apart from cases of extreme irritability, active delirium, meningism and meningitis, it is ordinarily better, while protecting the eyes with a screen, to admit daylight freely, unless the patient is definitely somnolent. In the quiet of the night, sleep is less likely to be disturbed. Moreover, treatment and nursing is arranged to give as long intervals of rest as possible at night—a matter demanding the close attention of the clinician, and one to which many statements in this article are relevant, especially as regards the suspension of particular methods of treatment, and, in some instances, the substitution of others, and also the control of affections which interfere with rest and sleep; *e. g.* vomiting, diarrhœa, cough, dyspnœa, cutaneous irritation, pain, pyrexia. Free ventilation favours sleep. For broken rest at night, the patient may be sponged in the evening with hot, tepid or cold water and given a hot drink. If sponging fails and the temperature is high, phenacetin (2 gr. for a child of four; 10 gr. for an adult) may be prescribed in addition, with or without alcohol. The last (1–2 drachms of brandy or whisky for a young child, ½ to 1 oz. for an adult) has special value as a soporific when there is great cardiac and general debility. It is more likely to act when the patient is an abstainer and is not having regular doses, and should be given in hot water, but not highly diluted. Simple treatment on these lines is apt to fail in definite insomnia, such as is common in toxic *Scarlet Fever* and *Smallpox*. The tepid pack may then succeed, if not contra-indicated by depression. Generally, hypnotics are required, and may be supplemented by the above measures. For all-round use: veronal, 2–10 gr. according to age, in hot milk. If it fails—

℞ Paraldehyd. ʒ iii
Extract. Glycyrrh. Liq. ʒ ii
Syrup. ℥ ss
Aq. ad ℥ iii

1 oz. for an adult, and less in proportion for a child, repeated once or twice at intervals of an hour if the patient does not sleep. Veronal (2–8 gr.) aids its action and may be prescribed with the second dose if the first has no effect. For persistent sleeplessness in children's cases—

℞ Syrup. Chloral ♏ xv
Sod. Bromid. gr. v
Aq. ad. ʒ ii

as a draught at the age of four with a drachm of whisky or brandy and half an ounce of water. When insomnia is a dangerous element in fever, and continues for, say, four days in spite of other treatment, morphia remains as a potent agent, not always safe, yet one which does good service in many cases, and seems sometimes to avert death: $\frac{1}{12}$ gr. hypodermically in later childhood, $\frac{1}{6}$ gr. for an adult. The early repetition of a dose is not advisable; if sleep is not caused in an hour, veronal (2–10 gr. according to age) will usually induce it.

12. **The Control of Delirium.**—Active delirium, most frequent in *Typhus*, toxic *Scarlet Fever* and *Smallpox*, mainly affects adults. Exhausting in itself, it disturbs sleep and is commonly accompanied by insomnia. Quietness is important in its control, and for this reason noisy cases should be separated. Its other treatment includes the application of an ice-bag or Leiter's tubes to the head, packing, sponging, and the administration of such drugs as are noticed above as useful in insomnia—preferably paraldehyde, with morphia for obstinate cases. In Smallpox and Typhus, patients may have to be watched; they may try to get out of bed, and have escaped from isolated quarters. Rarely, they are dangerous to themselves or others. Some have to be restrained by tying their wrists and ankles, wrapped in cotton-wool, to the side-rails of the bed with short lengths of bandage. In passive delirium, the chief indications are to secure sleep, if possible without drugs, and to support the heart.

13. **The Discouragement of Stupor and Coma.**—Deep stupor and coma—the latter specially a feature of *Typhus* and not uncommon in severe *Typhoid Fever*—react unfavourably on the heart. Their direct treatment is unsatisfactory, and reliance is rather to be placed on the early adoption of measures which tend to aid resistance to infection, to lessen intoxication as by keeping up the flow of urine, and to maintain the circulation. Strong black coffee (5 oz.

thrice daily) may be ordered in coma and oxygen administered for ten minutes every hour. The advisability of bleeding plethoric patients should be considered, particularly if the acute stage is nearing its end.

14. The Control of Convulsions.—As a febrile manifestation, convulsions may occur in infants and young children at the outset of various fevers, and end in heart-failure. A mustard bath should be given; if the seizures are prolonged and embarrass the breathing, chloroform in small quantity, oxygen continuously.

15. The Relief of Pain.—While acting directly on the circulation if severe, pain in various degrees tends to exhaust and to disturb sleep; when persistent, it cannot be ignored in serious cases of fever, even though it is slight. In particular cases, hot applications, counter-irritation, or a local or general anodyne may be required.

16. The Arrest of Hæmorrhage.—Bleeding, when insufficient in itself to be fatal, may still count as a factor contributing to the heart-failure of cases already critical, as occasionally happens in naso-faucial *Diphtheria* and often in *Typhoid Fever*. Prompt treatment in such cases may be vital. On the other hand, there are instances in which marked toxic symptoms improve after spontaneous hæmorrhage in Typhoid Fever. As a therapeutic measure, bleeding is adopted in uræmia, the pulmonary œdema of nephritis and in certain cases of pneumonia and coma.

17. The Avoidance of Elevation.—A striking feature of recent treatment in febrile cases is the care taken to keep the head low when there is vascular relaxation and the heart is acting feebly. Pillows are often dispensed with, the head resting on a soft, folded towel; a noticeable improvement in the pulse may ensue when this position is maintained, and the reverse result obtained if the head is raised. Sudden death has become rare in *Diphtheria* and other fevers, since patients have been systematically prevented from sitting up. The effect of this movement, however, need not be actual fainting with death as a possibility: in the vast majority of cases it is revealed by pallor and quickening of the pulse, which also loses volume and may become irregular or show increased irregularity. Slight as the change often is, the mischief wrought in a very short time may thenceforward be traceable in the course of a case towards recovery or death. Restless children may have to be kept down with a restraining belt, properly designed to allow movement without becoming displaced.

18. The Avoidance of Muscular Exertion.—Muscular stress is detrimental to the weakened heart even when the patient is lying down, and its effect may persist. Accordingly, methods of treatment and feeding may have to be altered or stopped in the former instance if they are resisted. Food, etc., should not be left where patients suffering from cardiac debility can reach out for them.

VI. The Bearing of Treatment on Related Forms of Febrile Disturbance

It is evident that direct and indirect relationships exist between local phases of the febrile state. One may intensify another, or there may be a mutual influence of this kind, while in some instances a single phase may be linked with several. Such processes could only be presented comprehensively as aspects of clinical pathology, but a recognition of the more important ones is implied in various methods of treatment embodied in the preceding pages. As a general fact, such interdependence, while often dangerous if ignored, has its favourable side for the therapeutist, since treatment effective in one direction may lead to a wider improvement. For this reason, the timely appreciation of the factors chiefly making for heart-failure in given cases and the most effective, if often indirect, methods of controlling them, is of great importance. It must be added that circulatory weakness may itself be concerned in certain processes which in turn tend to accentuate it; *e. g.* persistent vomiting, dyspnœa, hypostatic congestion of the lungs, renal efficiency, insomnia.

VII. The Direct Treatment of Cardiac Weakness

In the progressive weakening of the circulation, the question when stimulation of the heart should be commenced is often difficult to decide. The statement just made, however, points to the danger of undue delay, and it may be said that vicious circles involving the circulation generally call for the use of stimulants if the related processes cannot be alone effectively treated. In this connection, although to give alcohol before it is needed, and especially to push it prematurely, is objectionable, it is as a rule the drug first to be prescribed when stimulation will probably be necessary for more than a few days, and has the advantage that it can usually be continued later on if other agents are employed. For severe *Diphtheria* it may be ordered in the exudative stage, and is sometimes used for weeks thereafter. Its success as a stimulant depends on two conditions: the dose must be sufficient, the dilution not too great. Thus, in order to increase the dose, it may be better to prescribe it four-hourly rather than at shorter intervals; also, the amount of water, milk, etc., added to brandy or whisky should, if possible, not be more than 5 to 1. Four-hourly doses: 20 minims to 1 dr. for an infant, 1–2 dr. in the following years,

2–3 dr. in later childhood, $\frac{1}{2}$–1 oz. for adults. Always, the effect produced is the guide to further treatment: a fuller pulse, steadied more or less if irregular, not materially quickened and possibly slowed, indicates that alcohol is benefiting the patient, and that enough is being given. The minimum effective dose is the proper one, and it is only in exceptional instances that those mentioned have to be exceeded. Champagne, acting more transiently, may be ordered every two hours. It replaces brandy and whisky when these cause nausea or are rejected. Strychnine ranks with alcohol as a cardiac stimulant: $\frac{1}{150}$ gr. or less for an adult, $\frac{1}{300}$ gr. or less for a child, by hypodermic injection thrice daily or four-hourly, with $\frac{1}{60}$ gr. as a single dose in the former case, proportionately reduced in the latter. Firstly, however, in useful doses, it may have to be stopped after a few days because muscular twitching begins. Secondly, apart from its obvious toxic action, it may in the end affect the heart unfavourably; the pulse may improve on its withdrawal. While it has a deserved reputation for cardiac degeneration, the fact that it is a vaso-constrictor has to be taken into account when the heart is dilating. It is of special service in hypostatic congestion and extensive inflammatory affections of the lung as met with in the fevers. A third stimulant of value is camphor in the form of Curschmann's solution—two parts dissolved in three parts of sulphuric ether and seven of olive oil: 10–15 minims four-hourly for an adult, 5–8 minims for a child; 20–30 minims as an emergency dose. Having rarely to be stopped owing to restlessness and other mild toxic symptoms, it can be prescribed for several days continuously, either alone or with strychnine, or as a substitute for the latter if it is discontinued. Adrenalin (4–8 minims of a 1–1000 solution hypodermically every four hours) has been chiefly employed to sustain the circulation in *Diphtheria*, and the improvement observed at times to result in that disease is probably not comprised in a rise of blood pressure alone. Its administration should be commenced in severe cases when the local lesion is declining, if not sooner. Because of a possible rise in blood pressure, caution is required in its use when the heart is markedly degenerated and dilated. The theoretical advantage of strophanthus in the cardiac debility of fever is not realised in practice. Digitalis more often does harm than good. However, when a crisis is approaching, and particularly in lobar pneumonia at a late stage, it may be useful: 5–8 minims of the fresh tincture thrice daily or every four hours, the pulse being watched and the urine measured. The rapid infusion of normal salt solution has a place in the treatment of cardiac failure: average amount, one pint. A glass funnel or other container is hung over the patient to hold the solution, at a temperature of 105° F. to allow for cooling. The fluid passes by gravitation through a rubber tube and large-sized antitoxin needle into the subcutaneous tissue of the anterior axillary fold. Finally, oxygen, every half-hour, hour, or continuously, remains for cases which respond but slightly or not at all to other measures. Its administration should not be postponed until the patient is almost moribund.

VIII. Treatment during Convalescence

Cases lightly covered in the pyrexial stage (as in *Typhoid Fever*) may require more bedclothes when convalescence sets in; a cotton or linen nightdress may have to be changed for a woollen one. Adequately clothed and protected against draughts, most mild cases of any fever but the above may sit up in bed through the acute stage. Also excepting Typhoid Fever, patients after a straightforward attack of average severity can usually sit up on the fourth day of convalescence; in Typhoid Fever, on the tenth day at the earliest, and possibly not until some time in the third week. Following severe febrile disturbance in general, the interval depends chiefly on the state of the heart. While signs of degeneration persist or the pulse is markedly quickened or slowed, or remains irregular, permission to sit up is withheld. The most dangerous stage of faucial *Diphtheria* being nearly always post-febrile and frequently subsequent to the disappearance of the membrane, in severe attacks of this disease the patient may have to be kept lying down for many weeks, quite apart from the supervention of paralysis. The period during which patients sit up may vary from a day or two to a fortnight or longer, according to the general condition and the state of the heart. In *Chickenpox* they are ordinarily allowed to get up when it is apparent that no more vesicles are forming, and those last out have desiccated; in *Measles*, after the acute stage is ended and catarrh has disappeared; in *Rubella* when the temperature is normal and the rash has faded; in *Typhoid Fever* and *Typhus* when the patient can sit up in bed for the greater part of the day without tiring, and, in the former, the ulcerated intestine has had time to heal (see above); in *Diphtheria*, when the heart has recovered. Even mild cases of *Scarlet Fever* are better in bed for three weeks after the onset of illness, as the period during which nephritis is most likely to develop is then covered; this rule is followed at Plaistow Hospital. For *Smallpox* the time varies greatly. The mildest cases of Varioloid, without secondary fever, can be up when the character of the rash

becomes certain; on the other hand, after a confluent attack it is sometimes several weeks before a patient is strong enough to rise. When they first leave their bed, fever patients may have to spend some days, up to a week, or even longer, on a couch. In *Diphtheria*, *Scarlet Fever* and *Typhoid Fever*, lingering heart-weakness without obvious symptoms under rest conditions is not rare. However, pallor and slight dyspnœa on exertion may suggest its presence, and in some instances there is accentuation of the second aortic sound, irregularity, a short or weak first sound, reduplication, systolic bruits. Sudden deaths after supposed complete convalescence from *Typhoid Fever* and *Diphtheria* are on record, but are extremely rare; the ordinary result of permitting patients so affected to go about too soon is that their general health remains unsatisfactory. A good red wine at meals for adults, a tonic such as Easton's syrup, or for children, Syr. Fer. Phos. Co., and, in due course, a change to the country or seaside, are all beneficial to those who have recently recovered from a severe attack of fever. The last is specially indicated in *Measles* and *Whooping Cough* when debility persists or children are of poor physique. J. B.

INFLUENZA

Any attempt to lay down a general scheme of treatment to include all the various forms which influenza can assume would be an impossible task; but there are certain measures which seem to have met with general acceptance. Although universal approval cannot be regarded as infallible proof of the value of a particular line of treatment, it is interesting to find that since the sixteenth century the debilitating character of the disease has been looked upon as its chief danger. It was this which moved so ardent an advocate of venesection as Sir Thomas Watson to say that "the chief risk of mistake is that of being too busy with the lancet. Certainly those affected by this disorder do not well bear active depletion." Influenza is indeed best met with patient inactivity on the part of the victim, whilst the doctor takes the rôle of gaoler. In any epidemic of influenza, the fatal cases occur amongst those who struggle against the disease. Those who give in soonest get up earliest and suffer least from the after-effects. The most important part of the cure is that the patient must promptly go to bed. There is no merit in resistance; *cedendo victor abibis*. Experience warns us that the patient who insists on going about during the early stages of the disease is a danger to every one he meets owing to his virulent infectivity, and is adding to the perils which he himself will presently encounter. Prophylaxis against influenza appears to be impossible. The immunity conferred by an attack is very short-lived. Neither age, social station, nor environment offers any protection when the epidemic is abroad: with the sole exception that the suckling infant escapes. Even eucalyptus, camphor and other like "odoraments to smell to" do not save their votaries. In an ordinary mild attack characterised by sudden onset of pain in the back, aching limbs, eyes and head, with a rise of temperature to 101 or 102° F., no further treatment may be necessary than that the patient should go to bed and take a mild diaphoretic mixture to which may be added salicylate of soda—

Liq. Ammon. Acet ʒ ii
Sod. Salicyl. gr. x
Syr. Zingiberis ʒ i
Aq. Chloroformi ad ℥ i

every four hours.

Aspirin (Aceto-Salicylic Acid) is an excellent alternative: it may be given four-hourly, either in cachets (10 gr.), or in a mixture with mucilage of tragacanth. Salicin (10 gr.), Novaspirin (Methylene-citryl-salicylic acid) (10 gr.) and Salophen (acetyl-para-amido-salol) (10 gr.) are useful drugs of a similar kind. The ammoniated tincture of quinine, although often credited with almost specific powers, seems to be quite inert and incapable of relieving any of the discomforts of influenza. In fact, quinine in any form often adds a tinnitus of its own to the patient's sufferings. There is one exception, namely, quinine salicylate (5 gr.), which may be beneficial if the neuralgic pains are severe at the onset. It may be prescribed in suspension in water, or in cachets. For headache, phenacetin (10 gr.) given every four hours is a reliable remedy, but it should not be administered over long periods.

Phenazone in similar doses is equally efficacious but slightly more depressing. Lactophen (10 gr.) and Salipyrin (20 gr.) are also useful. Pyramidon (Di-methyl-amido-phenazone) (3 gr.) is a remarkable antipyretic, but sometimes causes unpleasant collapse even in small single doses. The urea derivatives, Veronal (Di-ethyl-malonyl-urea, or Barbitone B.P.) (5 gr.), Adalin (Bromo-diethyl-acetyl urea) (5 gr.), and Bromural (α-Brom-iso-valerianyl urea) (5 gr.), given in single doses (not to be repeated) act as sedatives, relieve headache and procure sleep; but this group is dangerously toxic.

Dover's powder (10 gr.) is a very good remedy to employ at the first onset of influenza; it relieves the general malaise and the headache, and usually secures refreshing sleep.

Diet.—At first there is usually complete anorexia. The patient may feel disinclined for even milk and soda-water; clear soups, broths

and meat extracts are more palatable and refreshing. Fruit, especially oranges, grapes and limes, are pleasant, and leave the mouth clean. Lemon drinks, barley and oatmeal gruel, especially when iced, often meet with approval. Farinaceous and starchy foods are not as a rule well digested; milk and milk puddings may be nauseous. The best way of giving milk is in the form of junket or whey, particularly the white-wine whey made with sherry instead of rennet. Eggs are not appreciated in any form in the early stages except under the guise of albumen water. An occasional egg-flip with brandy can sometimes be tolerated.

With the gradual return of the appetite fish and meat without vegetables may soon be given. They are generally preferred plainly cooked; a little boiled sole and a grilled mutton chop or cutlet without fat seem to find favour. A small slice of not over-cooked roast beef or mutton is sometimes eaten with relish. As the appetite is restored alcohol may with advantage be added to the diet; not in the grudging shape of an indifferent wine disguised by medication, but the best the cellar can provide : a warrantable champagne, a burgundy full bodied and well flavoured, or a port of known vintage. Thus, by appealing to the mind and the eye, the palate may be tempted to viands for which it feels little inclination.

Influenza frequently presents symptoms of a definitely localised nature and assumes one of four well-recognised types, namely, respiratory, nervous, gastro-intestinal and cardiac.

1. **Respiratory Type.**—In this form the brunt of the disease may fall upon any portion of the respiratory tract, from the nasal passages and accessory sinuses to the lungs and pleura. In addition to drugs intended to counteract the general effects, local treatment of appropriate kind is indicated. It is unnecessary to go too closely in this chapter into details of treatment of the rhinitis, laryngitis, bronchitis, bronchopneumonia and pleurisy of influenza. The treatment does not differ essentially from that proper to these complaints when due to other causes. The irritable cough of influenza without actual bronchitis is often very wearying to the patient, and may assume a spasmodic form resembling whooping cough. Heroin (Di-acetylmorphine or Diamorphine B.P.) is a valuable sedative for this cough, and may be given in the form of a syrup—

Heroin Hydrochloridi gr. $\frac{1}{16}$
Acidi Phosphorici Concentrati ♏ ss
Syrupi ℥ i

or in any of the excellent acetomorphine preparations. Glycerinum acetomorphinæ (= $\frac{1}{36}$ gr. in 1 dr. approx.), Elixir Acetomorphinæ et Terpini (= $\frac{1}{18}$ gr. and $\frac{5}{9}$ gr. of each in 1 dr.), or one of the following pastilles: Pastillus Acetomorphinæ ($\frac{1}{20}$ gr.); Pastillus Acetomorphinæ Comp. ($\frac{1}{32}$ gr.); P. Pini et Terpini et Acetomorphinæ ($\frac{1}{48}$ gr.); P. Terpini et Acetomorphinæ et Menthol ($\frac{1}{400}$ or $\frac{1}{100}$ gr. of Acetomorphine).

A linctus containing opium is useful, such as Gee's linctus (Tinct. Camphoræ Co., Oxymel Scillæ, Syrup Tolutani, equal parts, dose 1 dr. = Opium $\frac{1}{12}$ gr.). Steam inhalations with Eucalyptus, Tinct. Benzoin Co., or Ol. Pini Sylvestris, sometimes give great relief. If the cough assumes the spasmodic form, an adult may learn to control and stop it completely by voluntary effort.

The respiratory complications of influenza should never be made light of. Bronchitis, bronchopneumonia and pleurisy, however slight they at first appear, may prove both dangerous and long lasting. From the nasal mucosa the infection may spread to the accessory sinuses; a complication which should always be suspected and looked for by transillumination or exploratory puncture when persistent facial or frontal neuralgia is complained of.

2. **Nervous Type.** There is a multiplicity of forms included in this type. A rough grouping is possible into a class characterised by pain, myalgia and neuralgia, a class in which psychoses predominate and influenzal meningitis. Myalgia and neuralgia may be relieved by local application of heat, counter irritation, or anodyne liniments such as Linimentum or Glycerinum Belladonnæ, Lin. Aconiti, Belladonnæ et Chloroformi, or methyl salicylate. Occasionally the neuralgia may persist for months after the acute attack has passed. Fresh air, exercise and a generous diet are more valuable in such cases than drugs. It is in these cases that special caution should be exercised against the formation of a drug habit. Temporary cessation of the pain can be obtained by using morphia, opium, heroin, acetanilide, phenacetin, either with or without caffeine, phenazone, and many other well-known drugs, all of which should be avoided whenever possible. The psychoses must be treated as necessity dictates; but fresh air and gentle exercise without fatigue are the first essentials of the cure. It is most important that return to brain-work or the strain of business life should be forbidden whilst any sign of mental unbalance remains.

Meningitis.—Reports of the efficacy of vaccine therapy in the treatment of influenza have recently been published in many journals, and it certainly seems as though this line of treatment should be promptly adopted when the diagnosis can be established.

3. **Gastro-intestinal Type.**—Rest, warmth and starvation may be said to sum up the treatment of acute gastro-intestinal cases. The patients

may be able to take plain water and should do so if possible. Stimulants may be necessary if there is profound collapse. In the less-dangerous cases an initial dose of castor oil (½ oz.) with tincture of opium (15 min.) should be followed by a bismuth mixture to which may be added small doses of opium (Tinct. Opii, Pulv. Cretæ Aromat. Opio, Pulv. Kino Co. or Tinct. Chloroformi et Morphinæ Co.). Bismuth B-Naphtholate (20 gr.) is a particularly good preparation to use in the gastro-intestinal type of influenza. But constipation must be avoided.

Recovery is sometimes extraordinarily rapid, and after living for a day or two on water and peptonised milk the patient may demand a good dinner: and no ill-effects follow if the request is granted. In fact it may be made a general rule to feed up the patient as early as possible in any form of influenza.

If the tongue remains coated with fur, small doses of calomel and saline aperients are beneficial. Stimulants are sometimes necessary in this form of influenza; alcohol may be given with good effect.

4. **Cardiac Type.**—The cardiac enfeeblement produced by influenza is a common symptom which requires serious attention. It may either occur during the height of the attack or persist for many months as a grave sequel. Endocarditis, myocarditis or pericarditis may develop, but the most frequent manifestations are of the nature of irregularities in rhythm. Tachycardia, bradycardia or mere feebleness of action producing fainting attacks and palpitations sometimes continue to cause distress and anxiety. The best treatment for any of the cardiac symptoms is rest in bed, followed by the greatest caution in resuming the normal activities of life. Strychnine is most valuable in strengthening the feebly-beating heart, bromides with digitalis often steady any irregularity of action. The patient requires feeding up well, plenty of fresh air even though confined to bed, and the avoidance of worry.

After-Influenza.—The period of convalescence from influenza is so definite a morbid entity as to deserve some title better adapted to its characters than one which, like convalescence, implies a "beginning to be well." In the opinion of many sufferers from influenza the defervescence of the fever and the decline of the acute symptoms only marks the passage from an irksome malaise to a grimmer series of evils.

The prostration and lassitude are disproportionate to the length of time occupied by the actual illness. The convalescent patient nearly always experiences the feeling of "being good for nothing" during a considerable period. Treatment during this stage is difficult and may tax to its utmost the physician's resourcefulness.

The patient must not be allowed to lapse into the idle equanimity of the professional tramp, while at the same time excess of physical or mental exertion must be avoided. Change of climate and scenery, without the fatigue of foreign travel in tourist fashion, may be recommended. Motoring and cycling should not be permitted. Moderate walking or riding can be safely indulged in. The quiet rest that the country or a sheltered seaside village offer is the ideal cure. But this need not entail solitude and boredom. The cheerful companionship of men or books and the pleasures of the table moderately enjoyed will effect more than much physic. Fresh air blows influenza out of the system, and even storm and wet need not keep the patient indoors provided the clothing is suitable and fatigue is not incurred.

Add to this a tonic containing quinine, cinchona or quassia with nux vomica or strychnine, and nothing more may be required. If the appetite does not return and the tongue remains flabby and coated with white fur, a morning dose of Epsom or Carlsbad salts will improve the digestion. Neuralgia, neuritis and neuroses of all sorts following influenza must be treated symptomatically with an ever-present fear of establishing some drug habit.

It is of the utmost importance to bear in mind that those cases of influenza in which complete recovery is long delayed may demand a revision of diagnosis, for some unsuspected complication may be present. Of these, phthisis, nasal sinusitis, otitis media, endocarditis, phlebitis, Bright's disease, diabetes and even locomotor ataxia are the commonest and most likely to be overlooked. Lying previously latent, these may by influenza be insidiously roused to activity and during many months remain undiscovered. Not the least part of the successful treatment of influenza consists in discovering the presence of some other cause of continued ill-health.

Vaccine Therapy.—The practical difficulty which at present stands in the way of treating influenza successfully by means of vaccines consists in the great variety of organisms found in cases diagnosed as influenza. The world-wide pandemics are generally due to *Bacillus Influenzæ* taking on a parasitic rather than a saprophytic rôle; otherwise, the occasions on which *Bacillus Influenzæ* is the infecting agent are comparatively few. Influenzal colds and many limited epidemics are due to numerous other organisms, the chief among them being a *staphylococcus* of one sort or another or members of that group to which the *Micrococcus Catarrhalis* belongs. The attitude to adopt at the present time should invariably be to ascertain first of all the particular bacteria present in the nasal, faucial or bronchial secretions, and to administer, if thought advisable, vaccines in

strict accordance with the bacteriological findings. Neither experience nor reason justifies the administration of some stock "influenza" vaccine to a case designated, on clinical grounds alone, influenza. This is a mischievous form of empiricism which to-day is all too rife.

It cannot be over-emphasised that, in any epidemic, and even in any individual case, the organism may, without varying its identity, so alter as regards its virulence that the vaccines prepared at different times from it display the most extraordinarily diverse properties.

Nevertheless, such good results have been recorded from the vaccine treatment of so-called influenzal meningitis and other cases of infection by organisms giving the characteristic reactions of the influenzal bacillus that, advancing cautiously along this unexplored path, valuable therapeutic progress may be made. J. A. N.

ERYSIPELAS

While it is an advantage if the case can be transferred to a special ward, the usual precautions observed in septic cases are sufficient to prevent dissemination of erysipelas when this is not possible. Special bed-clothing, towels, handkerchiefs and feeding utensils are necessary; the hands of those applying dressings or washing the patients should be covered with sterile gloves, since direct contact is the method by which the disease is likely to be spread.

Care should also be taken to cover the lesion with some form of protective dressing, so as to prevent the patient from infecting other parts of his own body by means of his hands.

The Treatment of the Primary Focus of Infection. It frequently happens that no primary focus of infection can be seen, or that it may have healed before the patient comes under observation. But a careful search must be made for such a focus, which may be within the margins of the buccal or nasal orifices, the vagina or rectum. If a primary focus is discovered, the exudate must be bacteriologically examined. Any open wound should be dealt with by ordinary surgical methods such as the opening of abscesses, the scraping of sinuses, or the extraction of carious teeth.

As it may be necessary later to invoke the aid of an autogenous vaccine, an attempt should be made to isolate the micro-organism responsible, even if no primary focus can be found, although this often results in failure. As a rule the micro-organism cannot be isolated from the bullæ, where it is usually absent, and even if it is seen in films it fails to grow on cultivation. The usual method is to puncture the skin deeply with a needle or scalpel close to the spreading edge of the lesion; cultivations are then made from the serum which exudes, or from rubbings of the raw surface.

General Treatment.—The patient should be put to bed and constitutional treatment begun. Attention to the bowels is of primary importance; small doses of calomel followed within six hours by a full dose of magnesium sulphate or some other saline purge are indicated. If this fails an enema should be given. The diet should be light. In the milder forms of the disease this frequently suffices to allay the constitutional symptoms, which may disappear within twenty-four to forty-eight hours. As soon as the attack has passed off a generous diet should be given, as the high fever so commonly accompanying it is very exhausting. In elderly people especially, stimulants such as champagne and brandy are indicated, even during the attack. Liq. Strych. 3 min., combined with 10 min. of phosphoric acid in an ounce of chloroform water every four hours makes a useful stimulant. Special care is required in cases associated with chronic renal disease, as these are more liable to succumb to the infection; nitro-glycerin ($\frac{1}{200}-\frac{1}{100}$ gr.) has proved to be of service in these circumstances. Certain drugs have been regarded as being specific for the disease, such as Tr. Ferri. Perchlor. (10–30 min.), quinine and sodium salicylate; but the first is of little avail, while the two latter probably act merely as antipyretics.

Local Remedies.—Many local applications have been suggested, but the majority of cases get well without them. However, the affected part should always be protected both from the atmosphere and from possible contact with other parts of the patient's body in order to avoid auto-infection. Covering with sterile lint is all that is required. Starch powder or zinc oxide sprinkled on to this has a cooling and comforting effect. Cooling lotions, such as Lotio Plumbi c̄ Opio, moistening the lint have the additional advantage of keeping the tensely stretched skin softened, and thus relieving pain. A saturated solution of magnesium sulphate has been advocated for its osmotic effect on the swollen tissues. Certain antiseptic preparations may be used with or without previous scarification of the skin over the lesion; carbolised vaseline, ichthyol ointment spread on the lint, or iodex painted over the skin are of the best. A saturated solution of picric acid is advocated by many. Anti-streptococcic or normal horse serum applied locally may meet with success.

Attempts have been made to limit the spread of infection by injecting small quantities of the latter around the edge of the lesion; solution of carbolic acid (1–20) has been similarly used. Fomentations in any form should be avoided.

Certain other methods of treatment are

indicated in the severer forms of the disease. Lymphangitis, lymphadenitis, severe prolonged pyrexia, the isolation of streptococci from the blood stream or metastatic deposits, and the involvement of other organs call for serum or vaccine therapy. While it is true that erysipelas tends to a natural cure, it is wise to be ready with artificial means of inducing immunity.

Serum Therapy.—Mention has already been made of the use of serums as local dressing. For internal administration it is advisable to use the anti-pyogenes (anti-erysipelas) serum, which is prepared by immunising horses with the streptococcus pyogenes or a mixture of different strains of such. The advantage of this over the polyvalent variety depends on the fact that one of the forms of the streptococcus pyogenes is invariably responsible for erysipelas. Large doses should be given in the early stages of the disease. The initial dose should be 50 c.c. given into the subcutaneous tissues, followed by daily doses of 25 c.c. It may also be introduced into the circulatory system mixed with normal saline solution in a similar dose. It is essential that the saline solution should be prepared from freshly distilled water. The effect of the introduction of serum is often instantaneous, the temperature falling to normal within a few hours, and the infection abating at the same time. It must be remembered that in some cases there appears to be no appreciable effect.

Vaccine therapy.—The streptococcus used for the vaccine should if possible be isolated from the lesion; but if this cannot be done, a vaccine should be prepared from a mixture of stock virulent streptococcus pyogenes. A sensitised vaccine may also be used. (See article on *Vaccine and Serum Therapy*.) The dosage depends on the severity of the infection. In the early stages of the disease with marked toxæmic symptoms, but without evidence of bacteriæmia, doses from twenty-five to fifty millions dead streptococci may be given into the subcutaneous tissues, but in the more severe cases smaller doses, starting with one million and rising gradually in daily doses as indicated by the course of the disease should be tried. It is impossible to lay down definite rules as to dosage; broadly speaking it may be said that the more severe the infection the smaller should be the initial dose. Much larger doses of sensitised vaccines may be safely used even in severe cases; with these the intensive method as suggested by Fornet and Muller should be used, *e. g.* doses of ten, twenty-five and fifty millions given on three successive days. The results are variable. In some cases the appropriate dose will cause immediate abatement of the symptoms, with subsequent resolution; if this does not occur with the initial dose, it may follow subsequent inoculations. In other cases each inoculation will cause a marked improvement in the general condition of the patient, without improving the local condition. In yet others no obvious benefit will be obtained.

Treatment of Recurrences.—Recurrences are apt to follow an attack of erysipelas and may be very difficult to deal with. Prophylactic measures are of the first importance. The clothing should be thoroughly disinfected, the patient removed to another room as soon as the infection has abated, and a carbolic bath given. If there is still a primary focus of infection, it should be vigorously treated, then the affected teeth should be removed if there is pyorrhœa alveolaris, any septic condition of the nose should be attended to, chronic ulcers of the skin should be encouraged to heal and sequestra removed from the bottom of sinuses.

If these measures fail to prevent recurrences vaccine-therapy is always worthy of a trial.

Treatment of Associated Symptoms. — Local applications usually suffice to allay pain, but if these fail such drugs as morphine tartrate, $\frac{1}{4}$ gr., may be required hypodermically. Sleeplessness is frequently a troublesome symptom, for which the bromides or aspirin may be used.

Delirium combined with high fever will usually disappear after the use of antipyretic measures. Chloral hydrate is often useful in the more obstinate cases. W. G. B.

PNEUMONIA

The history of the treatment of Lobar Pneumonia before the time of Louis and Skoda is an unprofitable study save in so far as it serves to illustrate the Hippocratic maxim that experience is fallacious. Sir Thomas Watson little dreamt how posterity would come to judge his warning words when he wrote, "Very lately one most distinguished French writer, M. Louis, has endeavoured to show that venæsection has not much control over the progress or event of pneumonia; and I advert to his opinion on this subject merely to caution you against being misled by it; as you might otherwise be considering his well-merited reputation as an exact and faithful observer." The active plan of antiphlogistic treatment of pneumonia by copious bloodletting, mercury and tartar emetic has given place to the expectant method, and the modern therapy consists in endeavouring to maintain the patient's strength whilst the disease runs its course, which fortunately is as a rule short. In spite of much searching after a specific remedy wherewith to counteract directly the activity of the pneumococcus or minimise the effects of its toxines no reliable

cure for the disease has yet been discovered. The treatment resolves itself into two parts—general and symptomatic.

General

At the outset the surroundings and nursing of the patient demand attention. A large, airy and well-lighted room is necessary, where the patient may be kept in bed. The bed should not be too wide, nor the mattress too soft. The bed-clothes should be warm enough without being heavy, and in cold weather it is better to rely upon hot bottles rather than extra bed-clothes. A light flannel jacket or a so-called "pneumonia jacket" made of gamgee tissue is useful, as it enables the patient to be propped up in a sitting position without regard to covering the upper part of the body with bed-clothes. This is also convenient for the physician's examination of the chest. Adequate skilled nursing is of the utmost importance, and the use of the bed-pan is imperative. The number of persons in the room must be limited to one or two, conversation restricted and the patient allowed to talk as little as possible. Tepid sponging of the whole body once or twice a day is as a rule comforting even if the fever is not high. The mouth and nose should be kept carefully cleansed and the skin of the back tended with the usual precautions. The patient, if unable to move, should not be permitted to remain in one position too long at a time, nor allowed to slip down too low in the bed.

Diet.—The diet should be light and nutritious. Digestion is always impaired during the acute stages of the disease. Plain water, lemonade or lemon drinks should be given freely. Milk, either plain or with soda-water, peptonised milk, junket, whey and eggs either raw or lightly boiled, are the most suitable food. The addition of carbohydrates to the food in the form of cane- or milk-sugar should not be forgotten. Beef-tea, soups, broths and meat jellies or extracts are useful as stimulants, but they have no great nutritive value. Small quantities of prepared protein food powder may be added to the milk with advantage. The foods prepared from one of the cereals are useful by way of change and their digestion may be aided by the administration of taka-diastase or pancreatin.

Drugs.—No drug exercises any direct influence on the course of the disease. In the initial stages a mild diaphoretic mixture containing liquor ammoniæ acetatis may promote a sense of comfort and does no harm. Expectorants are useless and worry the patient. Free water-drinking increases the flow of urine and may assist in the elimination of toxines. At the onset it is well to open the bowels freely with calomel or blue pill followed by a saline. Afterwards drastic aperients should not be given, mild salines or simple enemata are preferable. Tympanites is a distressing and, in children, common symptom, due in part no doubt to the limited diaphragmatic movement, and in part to the constipation which accompanies the fever. Constipation may be avoided by water-drinking, but if distension occurs turpentine enemata or the use of a rectal tube will generally give relief. In pituitary extract we possess a most reliable remedy for tympanites.

Symptomatic Treatment

Pain.—The intense pain in the side at the onset of the disease may be relieved by linseed or linseed-and-mustard poultices, especially in children. The poultice should be applied to the side or base of the lung affected and should not encircle the whole chest so as to impede the already embarrassed movements of respiration. The poultice should be taken off before it gets cold and clammy, the skin should be dried and a pad of warm dry wool placed round the chest. Leeches (six to twelve) applied over the site of the pain or pleural friction may prove of great service. The continuous application of an ice-bag is a not unpleasant alternative, but it is sometimes difficult to keep it in contact with the chest without uncomfortably firm bandaging. A mustard leaf or blister is also useful. For the severest forms of pain a hypodermic injection of morphia ($\frac{1}{4}$ gr.) may be necessary. Dover's powder often gives very great relief in the initial stages of pneumonia where there is much pain, and is suitable for administration to children no less than to adults.

Toxæmia.—When the initial toxæmia is severe and the shock of the invasion profound, as often occurs in children, stimulants are necessary. Brandy, spirit of ether, Hoffman's anodyne, or sal volatile may be given by mouth, or hypodermic injections of strychnine or camphor (5 min. of a 10 per cent. solution of the latter in olive oil for children). During the later stages of the disease when the fever is at its height the toxæmia bears apparently little relation to the extent of the physical signs of pulmonary consolidation. Although this indication of the progress of the disease is one which the physician watches with the utmost care and maps out with geographical precision, it must nevertheless be admitted that the treatment is rarely influenced by the information so gained. This is true at least so long as the signs remain only indicative of solidification of the lung, no matter over how large an area. The prognosis may be influenced, but not the therapeutics of the case. On the one hand recovery may take

place in spite of the most extensive involvement of the lungs, whilst on the other hand heart failure often occurs with quite limited consolidation. The treatment of toxæmia consists in *hydrotherapy*, free water-drinking to flush the kidneys and avoid constipation, in sponging the whole body frequently with either hot, tepid or cold water, according to the preference of the individual patient or in water compresses (60° F.) to the chest. Stimulants, as described previously, may also be required when the toxæmia is profound.

The Heart.—It is a mistake to exhaust our battery of drugs in the routine stimulation of the heart in every case of pneumonia. Many patients will, if left wisely alone, make good recoveries. In determining whether stimulants are necessary, the guiding rule should be that "anything which weakens the heart weakens the first sound." The first heart sound must be diligently observed, since from its quality much information may be gained. In a failing heart the systolic and diastolic intervals tend to become equalised. Some degree of cardiac dilatation need not occasion alarm, it is perhaps an inevitable consequence of, and compensation for, the respiratory embarrassment. Digitalis is undoubtedly a useful drug, and the freshly made galenical preparations are better than the much-advertised proprietary derivatives. Ten minims of the (standardised) tincture may be given four-hourly. Ether, nux vomica and brandy are also useful. The latter is especially so in old persons and those accustomed to take it habitually. Hypodermic injections of strychnine (5–10 min. of the Injectio Strychnin. hypod. B.P. 1914) may be given. Injections of camphor (5–20 min. of a 20 per cent. solution in olive oil) provide one of the most valuable stimulants in pneumonia. Care must be taken to inject camphor into the deep tissues and not immediately under the skin. Camphor injections may be given frequently and over long periods. It is a good plan in severe cases of heart failure to employ alternately camphor and strychnine injections every two hours. Caffeine (5 gr.) acts well in pneumonia, and its effect is increased by administration in strong coffee. Ammonium carbonate (3–10 gr.) is an excellent cardiac tonic, which is least unpleasantly prescribed in milk; but unless the patient has already begun to expectorate, it may increase an ineffective and painful cough in a troublesome way. Although tincture of musk has gone out of fashion, there are some patients who respond to its administration in drachm doses quite surprisingly. If dilatation of the right side of the heart supervenes with great cyanosis, venesection (15–20 oz.) should be performed. Children and thin, ill-nourished adults tolerate bloodletting extremely badly and are rarely benefited thereby. Inhalation of oxygen sometimes produces good results, but on the whole the great expectations formed of this remedy have not been realised, except in children, who, for some reason, usually respond well to oxygen.

Pyrexia.—A certain degree of fever is part and parcel of pneumonia; it is not an unfavourable sign and no active measures need be adopted for reducing it. Apyretic pneumonia bodes ill for the patient. Antipyretic drugs, such as antipyrin, phenacetin, acetanilide, pyramidon and the like, do no good and are powerful cardiac depressants. If the fever is of such a height as to make the patient restless and sleepless, sponging with hot, tepid or cold water is the safest and best means to adopt for reducing the temperature. Ice-cradling is excellent, it does not disturb the patient and rarely fails to promote a feeling of comfort, allay restlessness and ensure sleep. The simple process of reducing the bed-clothes to a single sheet is often forgotten; patients with fever do not catch cold. An ice-bag continuously applied to the head with hot bottles about the feet and legs will often soothe a restless patient.

Delirium.—Great danger is to be apprehended from violent delirium, chiefly because of the physical exhaustion it entails. Experience shows that there are two types of delirium met with in pneumonia, alcoholic and toxæmic or pneumonic. Of these the first is by far the less dangerous. In alcoholic delirium, at any rate, mechanical restraint of the patient's movements by a sufficient number of skilful attendants is the best method of control. In either type of delirium, sedative drugs, although they may be necessary, are never harmless. Hyoscine ($\frac{1}{200}$–$\frac{1}{50}$ gr.), given hypodermically is the least harmful. Bromide of potassium and chloral are not safe; they increase cyanosis and profoundly depress the heart. Morphia does not deserve all the hard things that have been said of it. Provided the kidneys are excreting sufficient urea, and provided there is no great degree of cyanosis, a hypodermic injection of morphia ($\frac{1}{4}$ gr.) combined with strychnine ($\frac{1}{100}$ gr.) may be advantageously employed in the treatment of delirium. Dover's powder (10 gr.) is the best and safest preparation of opium to use in the milder types of pneumonic delirium.

Insomnia.—Sleeplessness without delirium is not common in pneumonia; if it should occur, paraldehyde (1 dr. in 1 oz. of Mist. Amygdalæ) is a remedy worth trying. Its drawback lies in its capricious action. It acts as an hypnotic in disappointingly few cases, but when it does act it is preferable to any other drug. Hyoscine, opium and morphia may be used with caution. The objections to bromide and chloral have been mentioned under the treatment of delirium.

Sulphonal, trional, tetronal and above all veronal are unreliable and dangerous. Sponging and ice-cradling will often promote sleep. Oxygen frequently acts like a charm in children, but a good nurse will get a child to sleep where drugs are of no avail.

Cough.—In the early stages of pneumonia the cough is distressing and unprofitable. It may be diminished and relieved by poulticing the chest, by the application of an icebag to the affected side, or by strapping the side. Simple demulcents may be given, or, if the cough is excessive and exhausting, Dover's powder, opium, morphia, codein or heroin (Heroin Hydrochloride Diamorphine hydrochloride B.P.) may prove useful. The early cough is due to pleurisy and there is no reason why it should not be checked. But in the later stages, when resolution has begun and there is some sputum to be expectorated, the cough is useful and should not be stopped unless it appears to be in excess of the patient's needs. When bronchitis is present the cough does good rather than harm. In these circumstances the cough should be assisted by expectorants. If the sputum is thick, tenacious and got rid of with difficulty, ammonium chloride or carbonate (3 gr.), guaiacol (1–5 min.), creosote (1–5 min.) and terpene hydrate (2–6 gr.), help to make the secretion more easily expectorated. Small doses of Vinum ipecacuanhæ (10 min.) or Vinum Antimoniale (10 min.) occasionally do good, as also does potassium iodide (5 gr.) in cases where the patient is able to cough but cannot dislodge the mucus; but these three latter remedies should not be given frequently, nor over periods of several days. They impair the appetite and digestion and depress the heart. Strychnine or nux vomica will often relieve the patient by enabling a stronger cough to perform with less effort the task of clearing the lungs of secretion. Steam-tents and bronchitis kettles scarcely ever do good in pneumonia, and an atmosphere heavily laden with moisture adds to the patient's respiratory difficulties.

Complications

Not the least important part of the treatment of pneumonia lies in the early recognition of certain complications.

Empyema is the complication whose early discovery is of the greatest moment to the patient. Unresolved pneumonia may occasionally exist, but it is a diagnosis with which no physician should rest content until established by necropsy. Most cases of unresolved pneumonia so diagnosed during life turn out to be cases of empyema. The assistance of the X-rays should always be sought to supplement the exploring syringe in cases suspected of being empyema or diagnosed as unresolved pneumonia. Early exploration on very equivocal physical signs is not only justifiable but imperative. Repeated explorations should follow a negative result; if the patient's condition and physical signs justify the suspicion of empyema a single negative exploration does not suffice to establish a contrary conclusion that pus is not present somewhere in the chest. Apical and interlobar empyemas are always puzzling, and a protracted case of pneumonia in a child is generally due to empyema, even though the physical signs do not suggest its presence. All cases of empyema should be treated by an early operation with resection of portions of one or more ribs and free drainage.

Serous effusion requiring aspiration hardly ever complicates pneumonia. The presence of a large serous effusion should always rouse a suspicion that the case is tuberculous in origin.

Gangrene of the lung is not invariably fatal; inhalations of creosote, guaiacol or turpentine may relieve the condition if the gangrene is localised and limited to a small area.

Abscess of the lung, if discovered, demands operation and drainage.

Otitis media is a common complication of pneumonia in children and must not be neglected. A discharge from the ear always requires treatment, but if the otitis can be discovered before perforation occurs a timely incision of the membrana tympani will often avert deafness and the many dangers of a chronic suppuration of the middle ear.

Ear-discharges in pneumonia are only too often treated with the light-hearted contempt bred of ignorance. The assistance of an aural surgeon should be sought at the first signs of otorrhœa. Chronic otorrhœa following pneumonia is a reproach to the physician.

Meningitis.—The treatment of pneumococcal meningitis has hitherto not proved encouraging. Possibly vaccine or serum therapy may eventually yield results as gratifying as those of Flexner's serum in cerebro-spinal meningitis.

Pericarditis.—The pericarditis which sometimes complicates pneumonia is unfortunately frequently purulent. Treatment is unsatisfactory and the prognosis bad. The pericardium has been opened and drained for pyo-pericardium. If there is not actually pus in the pericardium the inflammation is generally of a plastic type and may involve the mediastinum.

Endocarditis is a complication which if recognised can only be treated as in rheumatic cases, save that salicylates are not indicated.

Peritonitis is a rare complication which if generalised requires immediate laparotomy. The results of early operation are good, those of delayed operation fatally bad. A slighter localised peritonitis limited to the under surface of the diaphragm will probably escape recog-

nition, and so long as it remains localised does little harm. It will, in the majority of cases, be regarded as a localised pleurisy and receive equally appropriate treatment.

Arthritis.—A red, painful, swollen joint occurring in the course of, or during the convalescence from, an attack of pneumonia should be explored early with due attention to asepsis. Joints infected by the pneumococcus usually suppurate. They should be freely opened and drained if pus is discovered. A sound movable joint should result from the early diagnosis, and drainage of a suppurative pneumococcal arthritis.

Other rarer complications such as **phlebitis, nephritis** and **peripheral neuritis** do not differ in their therapeutic requirements from the same conditions excited by other causes.

Many of the complications of pneumonia are suppurative and require surgical operations. There is sometimes a tendency to hesitate to advise operation because of the desperate condition of the patient. No patient suffering from pneumonia should ever be regarded as too ill to have pus evacuated. In pneumonia an operation is borne well even if a general anæsthetic is contra-indicated. Under local anæsthesia operations of considerable magnitude can be performed. It is a mistake to delay a necessary operation until the patient is convalescent, the patient will probably not convalesce so long as he is harbouring pus.

Convalescence and After-Care

In an uncomplicated case where resolution proceeds normally the patient may be allowed to get up a week after the crisis. If the pulse becomes unduly rapid with exertion and movements, caution must be used; a simple measure of the heart's recovery of tone lies in the length of time taken by the pulse to regain its previous rate after being quickened by sitting up in bed. In a healthy convalescent the pulse-rate should steady down in two or three minutes at most. A low blood pressure (90 min. Hg. or less in an adult), indicates lack of tone in the heart-muscle. Rest, fresh air and tonics are the only remedies needed, plenty of good food is more important than anything else.

The after-care of pneumonia should entail as long a rest from work as possible with change of air to a mild, warm, dry climate. Whether pneumonia predisposes to phthisis or tuberculous subjects are unduly liable to pneumococcic infections, the fact should be realised that a large proportion of phthisical patients give a previous history of one or more attacks of lobar pneumonia.

Children appear particularly liable to repeated attacks of pneumonia; considerable care should be exercised with a child for some years after a first attack.

Specific Treatment

Although up to the present no great progress has been made in treating pneumonia either with vaccines or antitoxic sera, there is no reason to adopt a hostile attitude to remedies of this nature. Sometimes it has seemed that if administered in the earliest stages anti-pneumococcus serum has exercised a modifying influence upon the subsequent course of the disease. But this is a matter very difficult to judge, pneumonias vary so much in their effect upon individuals and in their own "epidemic constitutions." Vaccines prepared from the pneumococcus have so far failed to justify their use in general pneumococcic infections such as pneumonia, but in chronic local suppurations good effects have been reported.

The time is not yet ripe for expressing an opinion upon the possibilities of treating pneumonia by intravenous injection of bactericidal drugs. In ethyl-hydro-cuprein-hydrochlorate Morgenroth claims to have found a chemical agent which exerts its destroying effect upon the pneumococcus practically undiminished in serum. This drug administered intravenously has been found capable of curing pneumococcus septicæmia in mice, and provides, as Sir Almroth Wright has said, "the first demonstration of the possibility of preventing and curing a bacterial—as distinguished from a protozoal or spirochætal—infection by the administration of a drug." In the few human subjects to whom Morgenroth's drug has been administered its effects have proved it to be dangerously toxic and optico-neurotropic, while at the same time it has failed to affect the course of pneumonia. Wright suggests as an explanation that the consolidated lung offers a nidus to bacteria where they are safe from the deleterious effects of a drug in the blood-circulation that cannot penetrate to them. Hence the success in mice where the injection is septicæmic and the failure in human pneumonia where the drug has only restricted access to the infecting microbes. J. A. N.

UNDULANT OR MEDITERRANEAN FEVER

Distribution.—This disease is most common around the shores of the Mediterranean, but has lately extended into European countries (Portugal, Spain and France). Other endemic areas are present in India, China, North and South Africa, America, and Peru; in fact, the disease has now become world-wide.

Etiology.—It attacks all ages and both sexes, but generally has the highest incidence in women and young adults, occurring in all seasons, but particularly in the hot dry weather. The disease was frequently found in association

with typhoid in the Mediterranean, a person recovering from the former suffered often from a prolonged fever due to the latter infection.

The cause of the disease is the minute coccus, the *M. melitensis*, which produces an acute or chronic septicæmic condition. The organism may gain access to the body (1) by food, particularly in milk; (2) occasionally by infection through the skin and mucous membrane. Wherever goat's milk is a staple diet the disease tends to be endemic—goats being commonly affected though rarely showing any evidence of the disease. Cows also may be infected, and their milk can convey the dangerous organism. The infection is conveyed from man and animals chiefly by the urine, fæces and milk.

Symptomatology.—The disease may commence as an acute fever simulating typhoid and malaria, or it may run a subacute or chronic course, producing intense cachexia with anæmia and persistent neuritis. During the febrile state rheumatic-like symptoms may be present with some gastro-intestinal disturbance, excessive sweats, constipation, endocarditis, orchitis, lobular pneumonia or pulmonary œdema; nephritis and hæmorrhages are rare. The course of the disease extends on an average over three months, but it may be prolonged to two years. The nervous symptoms are generally marked : at first there are insomnia and slight delirium, then great depression and a tendency to nerve pains, such as sciatica and neuralgia, sometimes giving rise to a local paresis of groups of muscles. Cardio-vascular symptoms are common : irregular palpitations from slight mental or physical causes, rapidity of pulse with irregularity of force, volume and frequency. The changes in the blood are important; there is generally a reduction in the number of red cells and a low colour index—a marked reduction in the polynuclear cells and a relatively marked increase in the mononuclears giving rise to a general lowering of resistance to bacterial infections. Death may be brought about by hyperpyrexia, heart failure, and pulmonary complications.

The diagnosis may be made by the clinical symptoms : the long fever with rheumatic-like pains, sweats, constipation and cachexia, but most accurately by culture of the organism from the blood, or by agglutination reactions, which are present early and are given with high dilutions of the serum. The latter are specific in character if certain precautions are taken.

Occasionally the organism may be isolated from the urine, and the diagnosis confirmed thereby.

Prophylaxis.—As the exciting cause in the great majority of the cases is the entrance into the body of the micro-organism by milk, it is essential that in the endemic area this shall be rendered free from infection. In the Mediterranean and parts of South Africa, etc., goat's milk is almost universally used, and as this is now known to be so frequently infected, sterilisation must be effectively carried out. This can be done by boiling the milk, and that this has been effectively done can be ascertained by using the Ortol test. It must be remembered also that not only goat's milk, but cow's milk may be dangerous, and that the products of milk, such as cream, butter and cheese may convey infection; some cases have even been traced to ice-cream in Algeria. Infection in infants is conveyed by the mother's milk (Italy).

Treatment of the Disease.—Disinfection of all infected material from the patient must be carried out as in typhoid. In all cases of undulant fever it is important to remember that we are dealing with a specific disease over which we have no certain control and that it tends to run a very long course. It is of the very first importance so to conduct the treatment that the patient's strength shall be maintained by giving as much food as he can assimilate; we must also counteract the secondary anæmia, and symptoms must be relieved by appropriate measures. We may also attack the cause of the disease by means of vaccines.

With such a long and tedious disease good nursing is of great importance. In an acute case a comfortable bed in a well-ventilated room, which can be kept at an equable temperature with cheerful surroundings, is required.

A trained nurse is almost always necessary, for at first the course of the disease may be as severe as in a bad case of typhoid fever, giving rise to high pyrexia, gastric discomfort, slight delirium, insomnia, sweats and other symptoms of a severe toxæmia; here, then, a good nurse or nurses are required to carry out measures to keep down the fever, regulate the food, and attend to the comfort of the patient. The danger line of fever is often put at 103°, when tepid sponging is necessary; if the temperature rises to 104°, cold sponging; and above that a wet pack may be required. Great attention should be paid to the pulse and the condition of the skin; if the former is weak a stimulant should always be combined with the antipyretic measure; great care must be taken never to check sweats, if present, by hydrotherapy. A continued type of fever lasting three to four weeks, if uncontrolled, produces a marked effect upon the cardiac and nervous system, so that tachycardia and persistent neuritis appear. Constipation generally is a marked and early feature; as soon as the diagnosis has been made, small doses of calomel, saline purges, or better still, cascara and enemata, may be used. Sweats are frequently very severe and distressing, either

local or general; as in rheumatic fever, the patient should be kept between blankets and the skin frequently dried and powdered; this will materially decrease the discomfort. If rheumatic symptoms affecting the joints appear, as they are apt to do, hot opium fomentations, or belladonna liniment associated with perfect rest, gives the most relief. One of the most distressing symptoms in acute cases is the persistent insomnia. The patient should *never be allowed to pass sleepless nights.* Trional, sulphonal or other mild hypnotic preparations should be given. At first, the patient should be kept upon a restricted typhoid diet until the diagnosis is assured, when light soups, eggs, custard puddings, Benger's food and sanatogen may be given, always using the condition of the tongue as the main guide. If the tongue is fairly clean, the fever moderate, and the assimilation good, a very low diet is contra-indicated. Stimulants are not required, and should not be given at first; in the third, fourth or fifth week they will probably be most useful, and should be reserved to help a flagging heart enfeebled by continued pyrexia.

As to drugs, quinine is useless in large doses, but I have found that combined with chlorine (Burney Yeo's mixture) it did in some cases apparently shorten the pyrexia attacks; Hartigan recommends cyllin—but no drug has any specific effect. Digitalis, strychnine and ammonia may each render assistance in acute conditions when the toxæmia is most severe. Abundant cooling drinks are most gratifying; when the mouth and tongue are dry and foul, sulphurous acid as a wash is very beneficial, generally more so than boracic acid and myrrh, carbolic acid or listerine.

Both the condition of the lungs and kidneys should be watched from day to day. Anti-pyretics like phenacetin and antipyrin are generally to be avoided.

After the primary wave has passed off, each recurring attack of pyrexia increases the anæmia, the tendency to neuritis and the general cachexia; the patient loses weight steadily, becoming more and more depressed, and is liable to orchitis, boils, etc. The careful feeding becomes more and more important, and efforts should be made to combat the anæmia by mild iron preparations such as dialysed iron, Blaud's pills, etc., and ferro-glidine given with milk or with strychnine. Diffusible stimulants, such as brandy and champagne, will be helpful now. Later, when a low, hectic type of fever comes on, as in the third month and after, arsenic and iron are called for either by the mouth or by intra-muscular injections, and I have found preparations of yeast useful not only in increasing the number of white blood-cells, but also in reducing the tendency to neuritis; two drachms of fresh yeast may be given twice a day on bread and butter as a sandwich, or in milk; capsules of nucleic acid are also useful. In the chronic stages, massage of the wasted muscles should be used daily, and for the chronic neuritis high-frequency treatment is sometimes very beneficial. If pain is persistent, a liniment of aconite, belladonna, or camphor gives relief. In convalescence some malt alcoholic drinks may be given with food, such as good stout and porter, or port wine if preferred.

During convalescence warm clothing, fresh air and sunshine, with gentle exercise, must be insisted on, and frequently a change of surroundings brings about a cure when other means have failed; but the patient must be warned that a chill or over-exertion is liable to induce a relapse. Serum therapy has not given satisfactory results. A nucleo-proteid serum has been prepared by Donzello-Trambusti and is said to be effective, but much more evidence is required. Vaccines made of dead emulsions of the *M. melitensis* have been fairly tried. From a large series of cases in Haslar hospital and elsewhere I have found that their use was of no advantage in the acute stages of the disease, but during the chronic toxæmia with a low, irregular fever they appeared to cut short the disease. Their administration is scientifically justifiable and reasonable, for we know that the organism can remain alive for long periods in the spleen and other organs; therefore any measures are called for which increase the phagocytic activity of the cells in the blood tending to destroy the infecting agent. The two most important means to this end are appropriate vaccine therapy and the administration of yeast or nucleic acid. Scardo (Francesco) from experiments carried out at Rome on goats artificially infected with *M. melitensis*, obtained some good results with intravenous injections of corrosive sublimate (using Bacelli's formula). This method he is now going to apply to human cases with great hope of cutting short the fever.

A micrococcus paramelitensis has lately been described which is probably the cause of several anomalous forms of fever in the endemic area in which the ordinary serum diagnostic test has failed, and for which a special vaccine would be required. P. W. B.-S

POLIO-ENCEPHALO-MYELITIS, "POLIOMYELITIS"

Poliomyelitis and encephalitis is an acute specific fever communicable from individual to individual and must be treated as such. Unlike the other acute fevers, however, which for the most part rapidly clear up and leave no sequelæ, poliomyelitis, owing to damage done to the

nervous system during the acute stage, commonly leaves a residual paralysis of a variable degree.

The organism by which the infection is carried belongs to the group of "filterable viruses." It is present in the nasal and pharyngeal mucous membrane, and may remain in this situation for at least six months after the onset of the disease. It is present in the blood during the prodromal stage of the disease, and may experimentally be communicated from animal to animal by means of biting flies. It is also present in the intestinal mucus. The incubation period of the disease is experimentally eight to twelve days, but clinical evidence points to a shorter period, probably about four days. The infection may be carried by a third person.

General Treatment.—A case of acute poliomyelitis should be treated in regard to infection like a case of typhoid. In hospital "bed isolation" should be insisted on: in a house "room isolation." Swabs used for absorbing nasal and buccal secretion should be burnt and fæces and urine mixed with a disinfectant before being discharged down the drain. Bed-linen, articles of apparel and all utensils for food should be treated in the same manner as for a typhoid patient. In summer the risk of fly infection should be prevented by the use of a "mosquito net." Since the incubation period varies from eight to twelve days a *quarantine period* of at least *fourteen days* should be given to all contacts.

The *period of isolation* of the person infected should be at least twenty-one days, and he should be free from all nasal, ear or other discharge. The nasal and pharyngeal cavities should be syringed out with a solution of chlorine water or potassium permanganate 0·2 per cent. for a week before the termination of the period of isolation. There is evidence that "carriers" may occur, but the method of determining such is at present too difficult and uncertain to be of practical service, and since the infectivity of the disease is considerably less than diphtheria, the risk run is very slight if the above precautions are taken.

Treatment of the Acute Stage.—During the early stage of the disease *pain* is the symptom which demands the greatest attention. It is the symptom which renders these cases liable to be mistaken for rheumatism.

Absolute rest and freedom from jars is essential, and this is best secured by placing the patient on a water bed, the limbs being carefully supported in whatever position is most restful. Acetyl-salicylic acid, or salicin in 3–5 gr. doses every four hours will often help to allay the pain, but in some of the severest cases pain is only relieved by morphia. This drug needs, however, to be used with the greatest caution, and in small doses if the respiratory muscles are affected, and when given in such cases should be combined with $\frac{1}{200}$ gr. of atropine.

It is advisable to give 5–10 gr. of hexamethylenetetramine (urotropine) during the acute, and if possible during the prodromal, stage of the disease, for it has been shown experimentally that this drug passes into the cerebrospinal fluid and delays, if it does not always inhibit, the experimental infection of animals. It can safely be given in the above doses to quite young children.

Lumbar Puncture should always be performed during the acute stage, not only for diagnostic purposes, but also for the relief of pain. The cerebro-spinal fluid is always under increased pressure, and in many cases relief of pain is afforded by this means. Clark has shown experimentally that the injection of 1·5 c.c. of 1 in 1000 solution of epinephrin has a marked effect in limiting the spread of the disease, and this method of treatment might well be used in severe and ascending forms of poliomyelitis.

When the disease is of wide extent and the muscles of respiration and deglutition are affected, great care must be exercised in feeding the patient. If there is any evidence of failure of the glottis to close whilst the patient is being fed, it is advisable to feed the patient with a tube passed into the stomach.

After the acutest stage of the disease is past, which usually lasts from five to ten days, recovery begins to take place. The temperature becomes normal, pain ceases and the extent of the paralysis can be accurately determined. It is, however, most essential at this stage to keep the child at *absolute rest* for at least a month from the onset of the disease; for unless this is done there is a risk of the disease extending.

The important points in regard to treatment at this stage are the *prevention of contraction and deformities, the maintenance of the temperature of the limbs, and the stimulation of the muscles* so as to keep them in a good condition whilst the damaged neurons are recovering.

Contraction of muscles which produces deformity is best prevented by massage, passive and resistance movements and by the application of a *light splint* which will keep the leg in a normal position. *A "celluloid" splint* carefully moulded to the leg is most suitable for this purpose and should be worn both during the day and night.

Massage, active and passive movements, may be begun in the third or fourth week after the onset of the disease, and should be given twice a day for half an hour at a time.

The application of electricity in its various

forms is of considerable value, but it is important to use that form of current to which the paralysed muscles respond. The question as to the length of time for which the treatment by massage and electricity should be carried out is one which can only be decided in each individual case. In all severe cases it should be carried out for at least two years.

Warmth is most essential for the good recovery of the limbs affected, and this should be maintained by loose woollen stockings and overalls, friction to the skin, and by the application of heat.

In the later stages of the disease some *mechanical support* is often required in order to help the patient to walk, and also to prevent the occurrence of deformity. A well-fitted "celluloid" splint is probably the most convenient form, for it is light, it can be worn both during the day and night, and it keeps the affected muscles in a position of rest and thereby tends to hasten recovery.

In the second year after the onset of the disease a splint with a knee lock and spring attachment to reinforce the weak muscles will for many cases be more convenient. The celluloid splint is, however, by far the most convenient for cases in which there is weakness of the thoracic and back muscles, and also for those cases in which the arm muscles are affected.

Division of Tendons.—In cases in which deformity has arisen it may be necessary to shorten or lengthen tendons, and such treatment in conjunction with other measures is often most useful.

Transplantation of tendons, so-called muscle-grafting, has a limited application, but is of undoubted service in selected cases.

Resection of a joint so as to give a fixed instead of a flaccid joint is of some value in selected cases, but the age of the child, the duration and extent of the paralysis have to be carefully considered.

Nerve Resection and Reunion.—The object of this operation is to connect the proximal end of a degenerated nerve with the distal end of a nerve in connection with healthy nerve centres. The numbers of cases which are suitable for this form of treatment are few, and even those which are apparently suitable have for the most part given most disappointing results. The class of case most suitable is that in which the muscles of the arm supplied by the fifth root are paralysed, whilst those supplied by the sixth root are relatively normal. The operation should be performed before the sixth month after the onset of the disease, but no improvement is to be expected in the condition of the muscles for at least six months after the operation. It should be remembered that although the methods of treatment just mentioned are useful in individual cases the essential treatment lies in the maintenance of the nutrition of the limb by warmth, massage, and active and passive movements.

The line of treatment above described refers primarily to the common form of the disease in which the spinal cord is affected.

The affection of the cerebral hemisphere gives rise to a hemiplegia, the treatment of which should be by massage, and passive and active movements.

In those cases in which the cerebellum is affected ataxia is the leading feature, and this should be treated by a series of movements for re-educating the co-ordination of the limbs by hand and foot-step exercise. F. E. B.

SAPRÆMIA, SEPTICÆMIA AND PYÆMIA

Toxæmia is a general disorder dependent solely upon chemical poisoning of the body. It arises as the result of absorption of the products of bacterial activity, or of metabolic poisons, or of a poison from the alimentary tract. In this section, that form of toxæmia, sometimes termed *Sapræmia*, will alone be considered, in which the intoxication results from the absorption of the products of bacterial activity—their toxins and substances resulting from the disintegration of the tissues in which they thrive. In pure sapræmia, the organisms multiply and remain at the site of invasion and do not gain entrance to the general blood stream. Bacteria will flourish in tissues which are lacerated or bruised, infiltrated with blood or deprived of their blood supply, or injured with chemicals. Thus sapræmia is prone to occur in the puerperium, after burns, large wounds, operations involving the peritoneum, pleura or other serous cavity, and after the removal of tumours leaving ill-drained cavities containing blood and debris.

Septicæmia is that condition in which pathogenic micro-organisms invade the general blood stream and, becoming established, multiply therein. Such septicæmia may be met with—

1. In the course of certain infective fevers, *e. g.* typhoid fever, infective endocarditis, general tuberculosis, plague, as an essential part of the disease.

2. Following a definite local lesion; either primary, as in wound infection, or secondary, where the organism causing the septicæmia is other than that essentially concerned with the initial lesion—as, for example, streptococci in septic scarlet fever or in diphtheria.

3. Arising without any recognisable portal of entry—the so-called cryptogenetic infection.

It is with the two latter group sonly that we are concerned here. When, in the course of

such a general invasion of the blood and tissues, secondary foci of suppuration appear, the condition is called *Pyæmia*. It is seen not infrequently in the puerperium, or in the course of surgical diseases associated with suppuration, such as otitis media, phlebitis, osteomyelitis or bronchiectasis. It occurs occasionally when the external appearance of a wound is satisfactory, though on exploration a septic focus may be found in the depth. Commonly, septic thrombosis takes place in the veins leading from the infected area; the clot softens and portions becoming detached are carried away in the blood stream to lodge in the first capillaries they reach. Thus, where the systemic veins are involved, the lungs are generally the first, and it may be the only, organs in which secondary abscesses develop. Suppuration in the area drained by the portal vein may be followed by portal pyæmia.

The clinical distinctions between these three different results which may follow the entrance of bacteria into a wound are, however, more apparent than real, and the term septicæmia must be regarded as relative only; for it is highly probable that in sapræmia some bacteria do become carried off from the local lesion into the blood stream. In any given case it is often impossible, on clinical grounds, in the early stages to decide with certainty which variety of septic disease is present, and even later the line of demarcation may be very fine—indeed, the likelihood of other forms of septic mischief arising from the same cause must be constantly borne in mind.

Treatment

1. **General.**—The assistance of experienced nurses is one of the first essentials in the successful treatment of all cases of severe infection; in few conditions does so much depend upon the nurse in charge, not only for the immediate well-being of the patient, but also in the early recognition of some of the many complications which may arise. A second essential is an abundance of fresh air; the room, therefore, should be large, and the bed arranged as near the open window as is consistent with the avoidance of draught, or, whenever possible, should be pushed on to a balcony, the patient being protected by screens from draught; here, except, perhaps, in the coldest weather, the whole time may be spent, the patient being moved in only for washing, etc. For heavy patients an air- or water-bed is desirable. Septicæmic patients generally require propping up in bed, and the clothes should be light and warm. Bedsores form with great rapidity in this condition, and in order to avoid them the back and bony prominences and also the hair must receive most careful attention. The condition of the mouth also requires great care; if very foul, hydrogen peroxide is an excellent cleanser, while Listerine may be employed as a routine. A daily action of the bowels must be ensured, and the amount of urine passed in the twenty-four hours should be recorded.

(a) *Diet.*—The patient must be encouraged to take as much food as possible. When severely ill, milk, diluted, forms the chief article of the dietary, and an adult should take at least three pints in the twenty-four hours. The milk may be given plain, partly as milk jelly, junket, Benger's, or flavoured with coffee or tea. Barley water may be used as a diluent; soda-water is best avoided on account of its tendency to cause flatulence. In addition to the milk, three or more eggs should be taken—either beaten up in milk, or as boiled or baked custard, or as egg flip. Raw meat-juice, beef-tea, Brand's essence or Bovril, with a liberal addition of salt, should be given daily in small quantity. It should be remembered that a high temperature alone is no contra-indication to a liberal diet, and if the patient will take them, fish and chicken may be allowed throughout with a small quantity of alcohol, either as brandy (3 oz.) or stout or port wine. Feeds should be given every three hours, but the patient should on no account be wakened for a feed at night—though, if very ill, he will not sleep for longer than three hours at a time—and the amount lost may be easily made up later.

(b) *Drugs.*—Few drugs are required in the routine treatment, for the needs of no two cases are alike. Half an ounce of Ol. Ricini should be given as soon as possible. and in order to counteract the tendency of the stools to become offensive, an intestinal antiseptic, such as Izal oil (2 min.) or naphthalene tetrachloride (5 gr.) in capsules may be given twice a day. A mixture containing Tr. Digitalis (5 min.) should be given three times daily as soon as the diagnosis of septicæmia is made.

Several drugs have been employed in the hope of increasing the resisting powers of the body, unfortunately with little effect. Among such are collargol, nuclein, formalin and iodine, which have been injected intravenously.

2. **Local.**—The indication is to clean up as thoroughly as possible the local site of invasion, removing all foreign material in which the causal organisms flourish and abound, but in so doing to avoid as far as possible injury to the surrounding tissues. Efficient drainage must be secured, and the infected area should be freely irrigated with a mild antiseptic solution at a temperature of 100° F. For offensive wounds peroxide of hydrogen (5 vols.), potassium permanganate (1 in 1000), or tincture of iodine (1 oz. to 1 pint) are useful. For irrigation of cavities, such as the uterus, certain pro-

prietary products allied to carbolic acid—Lysol, Lysoform or Izal (1 in 200) may be employed. Douching of cavities may be followed speedily by a rise of temperature with or without a definite rigor; hæmorrhage, when it occurs, is usually slight. Normal saline solution is especially useful in dealing with large wound surfaces, and the tissues may be further cleansed by loosely packing with gauze soaked in 4 per cent. saline. The douche or irrigation should be frequently repeated; in the case of a superficial surface a bath may be employed for an hour or so at a time, fomentations being applied in the interval, but care must be taken lest the part become sodden through too-prolonged immersion. In bad cases the wound may be dressed with gauze soaked in normal horse serum or the appropriate anti-serum; this is of especial value when the infecting agent is one of the pyogenic cocci, or when the wound is slow to heal and granulations are late in appearing.

In cases of pure *sapræmia* this local treatment is usually followed by rapid improvement in the symptoms, but in *septicæmia* may lead to little or no amelioration of the patient's condition. The condition of the original wound in cases of septicæmia varies greatly. In some instances it may have healed completely, or show no marked local changes; but more frequently it is suppurating with raised inflamed margins, or there may be great swelling, much pain and marked lymphangitis. If small it should be excised; when situated on an extremity amputation may be necessary in order to save life. In not a few cases, chiefly those of streptococcal origin, the site of invasion may be obscure, the infecting organism gaining entrance through the middle ear, cranial air sinuses, mouth, biliary passages, intestinal tract or genito-urinary organs.

In *pyæmia*, if the infected area can be reached, the thrombosed veins should be excised and ligatured to prevent further embolism. Staphylococcal cases are not infrequently secondary to osteomyelitis and run a very rapid course; free incision must be made at once, and if widespread disease of medulla and periosteum is found, amputation performed without delay; when a doubtful area of inflammation is incised any exuding fluid should be taken, without exception, for bacteriological examination. If incision alone is performed in these cases of osteomyelitis, a positive blood-culture after the operation is a sure sign that amputation is imperative.

In the course of a pyæmia a sharp look-out must always be kept for the development of secondary abscesses, which begin to appear commonly between the fifth and tenth day. They are specially prone to occur in the lungs, spleen, kidneys, eye, joints, brain and areas subjected to pressure. In streptococcal cases the large joints are not infrequently involved; if treated by free and early evacuation of the pus little permanent damage may result. Occasionally such arthritis may subside without suppuration. Pathological dislocation is prevented by the application of splints, and later, massage. In staphylococcal infection the pleura, pericardium, kidneys and heart muscle are often affected. In the so-called chronic pyæmia multiple abscesses are met with, chiefly in the joints and cellular tissues. In all cases, except in moribund patients, the abscess should be opened as soon as detected; but in the lung the infarcted area is occasionally coughed up. Even after the fever has terminated and all local signs have disappeared, unless the patient puts on flesh and steadily gains strength, the greatest care must be exercised lest any surgical condition be overlooked. Especially when the patient has been treated with a vaccine, an abscess may form without any pain or tenderness, but will rapidly heal when the pus is evacuated.

One of the most rapid and satisfactory means at our disposal of assisting the body to be rid of the *toxæmia* is the subcutaneous or intravenous injection of freshly prepared sterile normal saline solution. It has the additional advantage of improving cardiac action and relieving thirst. One or more pints may be injected subcutaneously into the tissues of the flank or chest; more rapid absorption is obtained by introducing the fluid, as Woodman advises, through a Southey's canula inserted with the trocar vertically through the anterior axillary fold, the point of the canula coming to lie beneath the skin in the axilla. By this means two pints of fluid may be delivered in twenty minutes, leaving practically no swelling and causing very little pain when once the canula is inserted. A pint or thirty ounces may be injected into the median basilic vein in the cubital fossa; for this purpose a syringe with a three-way stopcock is the best to employ, as it does away with the necessity of cutting down to expose the vein, the needle being inserted just as in doing a blood-culture. The injection may be repeated daily so long as is necessary.

3. **Of Certain Special Symptoms.**—*Fever* of itself is not a serious sign, and an attempt to control it is only to be made when it makes the patient restless, or when it reaches a height above 104° F., which experience has shown may be associated with damage to the nervous system. The methods of control which are applicable are—

(*a*) Cradling, or ice cradling.

(*b*) Sponging with hot, tepid or cold water. The former is the more valuable, as it promotes surface evaporation.

(*c*) Wet packs—to be reserved for hyperpyrexia.

(*d*) Drugs. Fever is as a rule very little influenced by drugs, of which the most serviceable are quinine and cryogenin. The latter may be given in doses of 5 gr., three hourly, for three doses. In a *rigor* half an ounce of brandy in hot water is given as soon as the shivering begins, followed by hot coffee or milk. A hot blanket and well-protected hot-water bottles should be placed next to the patient, with extra blankets on the top. During the rigor the pulse may become imperceptible, but unless it remains impalpable at the wrist for more than three quarters of an hour, there is, as a rule, no cause for alarm. Should it remain absent for more than this time, a hypodermic injection of adrenalin (5 min. of 1 in 1000 solution), or pituitary extract ($\frac{1}{4}$ gr. = 1 ampoule, B. W. & Co.), or Liq. Strychninæ (5 min.) is required. In the rare event of these measures failing to restore the pulse, intravenous infusion of a pint of normal saline at a temperature of 100° F. will be necessary.

Sleeplessness is a serious symptom, and no effort must be spared in order to ensure plenty of sleep. Septicæmic patients are invariably "nervous" and apprehensive, and restlessness is often very marked. If not dependent on pain or any other obvious cause, alteration of the position of the patient in bed may be sufficient. Hot sponging is often efficacious, but has the great disadvantage of causing considerable inconvenience to the patient, and cannot be repeated. Hot milk or cocoa, an alkaline draught, hot whisky or brandy should be tried before resorting to drugs. Bromide and chloral hydrate, 10 gr. of each, may be given, repeated in an hour if necessary; sulphonal, heroin and nepenthe may be tried. Paraldehyde, given with gin or parmesan cheese is the safest of all soporifics in this condition. If sleeplessness is consequent on cough, 10–15 gr. of Dover's powder is often efficient. For pain in a wound, when aspirin and local applications of heat fail, a hypodermic injection of morphia with atropin will be necessary, but morphia should be withheld as long as possible, and if albuminuria be present, opium and its derivatives must be given with great caution.

Anæmia.—In septicæmia a steady fall in the number of the red cells is a very grave sign, and is met with especially when the infecting organism is streptococcus pyogenes. For its prevention a preparation of iron may be given by the mouth; but when hæmolysis is established it is preferable, in the majority of cases, to give a solution containing a grain of arsenite of iron hypodermically once or twice a day, with hæmoglobin (5 gr. t.d.s.) and extra-raw meat-juice by the mouth.

Distension.—The rectal tube may be employed for half an hour or so, four hourly. If this fails an enema of turpentine, or of asafœtida, or a mixture of both, should be tried. In addition to either measure, a hypodermic injection of physostigmine sulphate, or salicylate ($\frac{1}{100}$ gr.) may be given, and repeated four hourly for four doses.

Vomiting may be an early sign of peritonitis. If this cause can be excluded, give castor oil to begin with, followed by Sod. Bicarb., 1 dr., in $\frac{1}{2}$ pint of hot water. The quantity of milk must be diminished, and further diluted with lime water, barley water or coffee. Koumiss No. 1 may be substituted for the milk. Meat extracts are often retained when other foods are returned. If these measures fail, a mustard poultice or leaf applied to the epigastrium, or Tr. Iodi, 1 min. in $\frac{1}{2}$ oz. of water, may be tried every hour, for twelve doses, if required. In persistent vomiting it is necessary to stop all nourishment by the mouth and give a solution of glucose (1 oz. to 1 pint) either subcutaneously or by the rectum. When the vomiting ceases, a mixture containing hydrocyanic acid and bismuth salicylate may be helpful.

Diarrhœa may be of toxic origin, or due to some dietary indiscretion. The former is of serious import; Ol. Ricini, $\frac{1}{2}$ oz., Tr. Opii, 5 min., with brandy, 2 dr., should be given at once. The Izal oil may be increased to 4 min. four hourly. The diet must be diluted, and cold milky articles, sour milk, lime water or black coffee given. Raw arrowroot made to a paste with water and brandy, 2 dr. is often very efficacious. If the symptom persists, a starch and opium enema or rectal lavage with boracic lotion may be tried.

Cough.—The patient should be turned every two hours, to prevent pulmonary œdema. Hot milk or lemon drinks, liquorice lozenges or a heroin linctus will often afford relief. A well-made linseed poultice is the best application for pain in the chest, and is greatly to be preferred to leeches in these septic conditions.

Cardiac Failure.—It is on this that the fatal event in a septicæmia often depends. At the earliest sign of dilatation of the heart the quantity of brandy given in the twenty-four hours is to be increased to 4 oz., $\frac{1}{2}$ oz. being given three hourly, or, if the patient prefers it, an equal volume of champagne. When other circumstances allow it, the foot of the bed should be raised. Caffein sometimes works well, but is apt to cause insomnia. In "acute" failure, Curschman's solution (camphor 2, ether 1, olive oil, 7) 10–15 min. hypodermically, can be kept on for a long time at four-hourly intervals. Pituitary extract, $\frac{1}{4}$ gr. (1 ampoule, B. W. & Co.), is more lasting in its effect than Adrenalin, 5 min. (1 in 1000). The heart's action is often greatly improved by the administration of saline, or

better still of Ringer's solution (Soloid Saline Co. No. 2, B. W. & Co.) either subcutaneously or intravenously (*v. s.*).

Thrombosis of veins in the extremities, not infective in origin, occasionally occurs. The affected limb should be immobolised on a pillow between sandbags, the bed-clothes being raised over a cradle. The pain may be relieved by hot fomentations, or by painting with a mixture of equal parts of camphor, menthol and chloral. After six weeks, gentle massage with passive movements may be started.

Suppression of Urine and Renal Infarction.—The application of hot cloths and fomentations to the loins may serve to re-establish the urinary flow. If this fails, dry cupping and saline infusion may be tried. Caffein and theocin sodium acetate are not desirable on account of the extra strain they throw on the kidney. In renal infarction, urotropine, 10 gr., in water, 5 oz., may be given with citrates three times a day.

Specific Treatment

A valuable addition to the above methods of treatment lies in the employment of the appropriate vaccine or anti-serum, or both. A *vaccine* is a suspension of dead bacteria in normal saline solution. An *autogenous vaccine* is one prepared from the micro-organism isolated from the infected individual himself. A *stock vaccine* is one prepared from an organism isolated from a similar case of infection. A *sensitised vaccine* is a suspension in saline of a micro-organism which has been in contact with its specific anti-serum—a combination is thereby formed between the bacterium and its antibody, with the result that after its administration the "negative phase" is largely eliminated, so that larger doses may be employed, leading to an increased development of immunity. Such sensitised vaccine may be prepared from the organism isolated from the patient, *i. e.* autogenous, or "stock."

An *anti-serum* is one obtained from an animal, usually a horse, highly immunised against a particular organism, or group of organisms or toxin, by repeated injection therewith.

Before specific treatment—that is, treatment by vaccine or antisera—is carried out, exact diagnosis from a bacteriological point of view is essential. The methods of identifying a bacterial infection are—

1. *Direct*—that is, the isolation of the causal organism, or—

2. *Indirect*—that is, the identification of a specific antibody.

The former is by far the more valuable and can always be employed in cases of *septicæmia* and *pyæmia.* Films and cultures are made from the original wound or focus, where possible, especially from beneath a scab. In taking cultures from the uterus, or other cavity, the greatest care must be exercised lest material other than that from the infected site is obtained. For this purpose, the employment of some simple apparatus, such as Western's modification of Döderlein's speculum is helpful. This consists of a tube, capped at one end with thin rubber, sliding within another tube; the whole being sterilised before use. The outer tube is passed through the cervix, the inner being then inserted, while the platinum wire is finally passed through the rubber into the uterine cavity, all danger of contamination being thereby avoided.

The film preparation must on no account be omitted, for from its examination is determined the nature, varieties and relative abundance of the organism or organisms present, and the method to be adopted in the making of cultures.

Occasionally the wound at which the micro-organism has gained entrance has healed before the onset of septicæmic symptoms; in such cases it should be opened with strict aseptic precautions, and any fluid found—whether serous or purulent—taken for cultivation. In the event of failure at the initial site of infection, or where that is contaminated by the presence of a large variety of bacteria, the lymph glands draining the area, if enlarged and readily accessible, should be punctured with a needle attached to a hypodermic syringe and any juice obtained cultivated.

In *pyæmia*, the causal microbe may usually be isolated without difficulty from a secondary focus of suppuration, where previous efforts have proved unsuccessful. If these means fail, a blood-culture must be undertaken—and it is only in this way that the existence of a septicæmia, and its nature if present, can with certainty be established.

In those cases in which the site of invasion is not at once apparent, any such condition as suppuration in the middle ear or cranial air sinuses, cholecystitis, appendicitis or pyelitis must be carefully excluded as a possible source of infection.

Vaccine Treatment.—With regard to the dosage and frequency of administration of a vaccine in cases of septicæmia and pyæmia, a careful consideration of the general clinical condition of the patient must be the chief guide. In general, the more acute the case and the more widespread the infection, the smaller should be the dose employed. The doses given here are those which have been used in the treatment of average adult cases, the vaccine being given hypodermically in all instances. Serum and vaccine are often given coincidently with marked benefit.

If an ordinary vaccine is employed in *strepto-*

coccal septicæmia, the initial dose should not exceed 25 million, which if all goes well, may be repeated in four days; subsequently the dose is increased. At St. Bartholomew's Hospital considerable success has attended the use of *sensitised vaccine* in the treatment of streptococcal septicæmia. Its introduction is, however, too recent for any definite expression of opinion to be made as to its value. To an adult, three doses of 100, 250 and 1000 million are given subcutaneously on successive days as soon as the diagnosis is made. The toxicity of the organism being so largely neutralised in the process of sensitisation, this relatively large dose gives rise to very slight reaction.

Staphylococci are sensitised with difficulty; the initial dose of an unsensitised vaccine may be 50 million, repeated four days later and subsequently increased.

Though septicæmia is commonly due to infection by either a streptococcus or staphylococcus pyogenes, other micro-organisms are occasionally responsible for the condition. Such, for example, are the gonococcus, colon bacillus and influenza bacillus. In the treatment of these generalised infections by vaccine, the initial dose should not exceed 5 million; an injection may be given on three successive days of 5, 10 and 25 million. The gonococcus and colon bacillus can be "sensitised," but so far no serum is available for sensitising the influenza bacillus.

The general condition of the patient may show marked improvement under the influence of vaccine, without there being any coincident fall in the temperature.

Serum Treatment is of especial use in combating infections due to the pyogenic cocci. The serum may be administered by a variety of routes. The healing of unhealthy callous wounds is often expedited by dressing them with gauze soaked in normal horse or specific antiserum, and after any surgical measure, such as clearing out the uterus, anti-streptococcus serum may be applied to the raw area. The *intravenous* administration of serum should be reserved for those cases in which the full effect of the dose is immediately required; anti-streptococcus pyogenes — not polyvalent — serum, given by this route early in a case of streptococcus septicæmia is not infrequently followed by very great improvement in the symptoms, but later in the course of the disease the effect is less marked. Intravenous injection of serum is not uncommonly followed within half an hour by a rigor, and in such conditions as puerperal septicæmia, when there is already a septic thrombosis of veins, the inoculation may prove the starting-point of a series of perhaps daily rigors, where such have been absent before. Twenty-five or fifty c.c. are given in a pint of normal saline solution—freshly distilled water is essential in the preparation of the latter. If the *subcutaneous* route is chosen, 25 c.c. may be injected daily with strict aseptic precautions. The possibility of anaphylactic shock arising should always be borne in mind, especially when the dose is given intravenously to a patient who has been treated with serum before. In cases of *puerperal infection* the routine treatment at St. Bartholomew's is as follows: If the temperature rises and the uterus is at all bulky, before the lochia become offensive an anæsthetic is given and the uterus explored. Films are made from the uterine contents and immediately examined; cultures on blood-agar are taken at the same time. If a streptococcus is found in the film, a blood-culture is made, and 25 c.c. anti-streptococcus pyogenes serum in a pint of normal saline is given intravenously, followed by two subcutaneous injections of 25 c.c. at intervals of twelve hours. Should the temperature remain above normal after clearing out the uterus, a three-day course of stock sensitised streptococcus pyogenes vaccine is given as well. The cultures, if positive, are always kept, though an autogenous sensitised vaccine is but rarely employed.

If sensitised vaccine is available it is well to give it straight away; but if the patient is suffering from profound toxic effects, the indication is rather for serum, but in such instances it is advisable to give sensitised vaccine as well, for the effect of the serum is short-lived. If, however, there is no marked toxæmia sensitised vaccine alone has often proved sufficient.

When sensitised vaccine is not available, good effects have been known to follow the administration of vaccine and serum together—10 million killed cocci and 25 c.c. antiserum being injected subcutaneously. A. E. G.

RHEUMATIC FEVER

As rheumatic fever is now regarded as the result of infection by a specific organism, the treatment which is common to the acute specific fevers should be carried out, save that isolation is not required. During the whole of the febrile stage, and for some time afterwards, the patient should be kept in bed, in a large and well-ventilated room with a steady temperature of from 60° to 62° F. The body and bed-clothes should be sufficiently thick to prevent any chilling of the body, and preferably the patient will lie in a flannel sleeping-suit and between blankets. As sweating is often a marked feature, and is to be encouraged, the skin should be sponged with hot water at least twice a day, and the water may be rendered alkaline by the addition of carbonate of soda.

The body flannels must be changed as often as they become damp from the perspiration, so as to avoid the risk of a surface chill.

The toilet of the throat and mouth must be attended to by the free use of some mild antiseptic lotion containing boracic acid, or listerine, or Condy's fluid. In those cases in which the gums or the tonsils are in an unhealthy condition, local disinfection by means of carbolic acid, or Izal, or boroglyceride must be carried out during the illness. Owing to the arthritic pain usually present the question of complete rest in bed is easily settled in the case of adults, but in the case of children pain in the limbs may be trifling. It is none the less essential in all cases to maintain complete rest in the recumbent position through the whole of the pyrexial stage.

As thirst is usually present, water should be given freely. It is one of the best means of encouraging elimination of the poison. Potash water, thin barley water, lemonade or imperial drink flavoured with lemon or barley sugar are all admissible, and may be used according to the patient's preference.

During the pyrexial stage the diet should be fluid and light and given at regular intervals, say, every two or three hours. There should be no attempt to feed up the patient. Milk and water, Benger's food and milk, chicken-tea, and strained vegetable soups give a sufficient variety. Beef-tea, meat essences and meat jellies are better avoided. A cup of weak tea is probably harmless and is found to be very refreshing by most patients. Alcohol is better avoided save in the case of patients who are debilitated from other causes.

The **medicinal treatment** of rheumatic fever is of great importance because we have in salicylate of soda a drug which has a much more specific action than is attainable in the case of most fevers. Formerly the alkaline treatment prevailed and large doses of the salts of sodium and potassium were given, but it was difficult to determine any precise benefit from their use. The definite action of salicylate of soda in lowering the temperature, relieving the pain, and reducing the effusion into the joints is undoubted. This is a matter of everyday experience, but yet the specific action of the salicylate is denied by some. It is no mere antipyretic action, because not only is the fever permanently reduced in the majority of cases, but the arthritic pain and effusion are also removed. So reliable is the action of the salicylate that if I do not obtain this definite improvement within two or three days I begin to doubt the correctness of my diagnosis, and suspect the existence of pyæmia, or septicæmia, or acute rheumatoid arthritis. Again, it is sometimes stated that although certain symptoms of rheumatic fever are relieved by salicylates, carditis is neither prevented nor cured by their means. As a matter of clinical experience it will be found that carditis does not usually develop in a patient treated early with full doses of salicylate of soda. The very marked tendency in rheumatic infection to inflammation of the heart is well known, and the serious effects of this complication are an everyday experience in practice, but such effects are not common in those cases which have been treated early and thoroughly and sufficiently long in the acute stage of rheumatism with salicylate of soda.

Always keeping in view the liability to rheumatic carditis we shall probably find that our two best preventive measures are complete rest and salicylate of soda. The cure of rheumatic carditis by salicylates is another question. While an active pericarditis will often subside as the direct result of salicylate treatment we cannot observe the same result in a damaged valve or myocardium. But these damaged tissues will certainly be placed in a much better position for recovery by supplying them with blood freed from rheumatic toxins and organisms, and this is best produced by means of salicylates. While we do not expect such a marked effect in active valvulitis or myocarditis as in some other rheumatic lesions, we must not be deterred from persisting with the salicylate treatment in such cases. The old view that salicylates did harm in the case of active carditis has now been dropped as no evidence was forthcoming of any such result. It has probably occurred to others, as to myself, to find an active recurrence of rheumatic symptoms in a patient who had been relieved of all symptoms by means of salicylate of soda and who was still taking the drug. I do not know the explanation of this, but I have seen a similar occurrence in cases of syphilis, where marked benefit was being obtained by means of mercury and yet fresh lesions occurred during the treatment. Such occurrences are too exceptional to shake our belief in the efficiency of well-tried drugs like mercury and salicylate of soda.

The administration of salicylate of soda should be begun as early as possible in the attack. For an adult from 90 to 120 gr. in the course of twenty-four hours, and for a child of ten from 40 to 60 gr. will be sufficient in the majority of cases. The medicine should be administered every four hours in doses of 15 to 20 gr., and within forty-eight hours the temperature will probably have reached normal. When this stage has been reached the dose may be reduced to two-thirds, and in a few days to one-half of the original amount. The exact dose required must be determined accord-

ing to the conditions present in the patient. In a severe attack in a healthy subject it may be advisable to push the drug at an early stage, giving 20 gr. every two hours until some effect has been produced on the fever and pain. It is not advisable to discontinue the drug on the cessation of fever and other active symptoms. One aims at eliminating the poison as completely as possible from the system, and for this purpose the salicylate should be continued to the amount of a drachm daily for some weeks. It is a good rule to keep on with the drug as long as the patient is in bed, but I believe it is also beneficial to intermit the use of the salicylate for a few days at a time during this period. Custom has lately favoured the addition of an alkali, such as bicarbonate of soda, to the salicylate in doses equal to or double the amount of the latter drug. It has been advised with a view to prevent the symptoms of acidosis or acid intoxication which sometimes followed the administration of salicylates. As marked acidity of the urine is also characteristic of rheumatic fever the free use of alkalies is probably beneficial. I do not think that enormous doses of bicarbonate of soda are required, but that from one to two drachms in the day, in combination with the salicylate of soda, will be found to be beneficial in the acute stage and smaller doses in the convalescent stage. Enough has probably been given when a slight alkalinity of the urine is maintained. As rheumatic fever is sometimes characterised by relapses, recourse should be had at once to full doses of salicylate of soda and an alkali on a recurrence of fever or joint pains.

As a rule salicylate of soda is well tolerated, but some patients suffer early from nausea, vomiting and depression. When the disturbance appears to be gastro-intestinal in origin, an attempt may be made to remedy this by giving the dose more frequently and in smaller amounts at a time, 5 to 10 gr. every two hours, well diluted with water. In some cases it may be found that the drug is impure and has caused the gastric disturbance. The natural salt is preferred by some to the synthetic preparation, and while it may suit better those patients with gastric intolerance, for general purposes the synthetic preparation has been found quite efficient. Intolerance of the salicylate may be manifested early by headache and buzzing in the ears. This is undoubtedly an idiosyncrasy in certain people, more especially those of the neurotic temperament. In such cases salicin in 15 gr. doses or acetyl-salicylic acid in 10 gr. doses may be tried. As regards the general use of acetyl-salicylic acid in the routine treatment of rheumatic fever I cannot find that it has any advantage over salicylate of soda. Its chief characteristic, the relief of pain, may be taken advantage of in specially painful forms of the disease by giving it occasionally in place of the dose of salicylate of soda. There are certain drawbacks to the use of acetyl-salicylic acid. It is very insoluble in water and it is broken up in the presence of an alkali. Under the name of aspirin it is largely used as a domestic remedy for headache and pains of all kinds, and the physician may suffer in the estimation of the patient if he employs such a common remedy.

A valuable paper on the subject of the action of salicylic acid and organically allied bodies in rheumatic fever by Prof. Ralph Stockman has appeared recently (*Brit. Med. Journal*, 1913, I. 597), and the following observations are taken from this reliable source. *Benzoic acid* or *sodium benzoate* given in 15 to 20 gr. doses hourly or two hourly is effective, and its action is similar to that of salicylate of soda, but very much weaker. *Salicylic acid* in 15 or 20 gr. doses every four hours may be regarded as equally efficacious with salicylate of soda, but the latter has the advantages of being more soluble and less irritating to the stomach. *Saligenin* is chemically the alcohol of which salicylic acid is the corresponding acid. He treated four cases with it in doses of 10 gr. every two hours, and found its action to be rapid and satisfactory. A good deal of perspiration followed its use and two of the cases suffered from deafness. *Salicin* is the glucoside of saligenin and yields only 43 per cent. of its weight of salicylic acid, so that the necessary dose is twice as large as that of salicylate of soda. Given in 20 gr. doses hourly or 30 gr. every two or three hours, its action in rheumatic fever is highly satisfactory. On the other hand, Dr. Stockman found that a number of drugs when given in medicinal doses were quite ineffective in rheumatic fever. Amongst these may be mentioned *phenol*, *salol*, *quinine salicylate*, *glycosal* and *cinnamic acid*. The reason of the uselessness of these drugs he traces to the absence or small amount of salicylic acid which they contain or which they develop in the body.

Within recent years it has been asserted that salicylate of soda is not usually given in sufficiently large doses to obtain the greatest benefit. The amount recommended has been from 200 to 400 gr. daily, and even larger amounts have been employed. The dangers in connection with excessive doses of salicylate of soda are admitted by all who have used them. In many cases the patient is seized with sickness and vomiting and so escapes the risk of poisoning. In other cases the drug is excreted so rapidly by the kidneys that no harm follows,

but if the kidneys are functionally impaired the risk is a real one. If the drug is retained in the system, the tendency to acid intoxication is always present, especially in the young, and a fatal issue will so definitely follow the continued use of the drug that elaborate precautions have to be taken to avoid this. It is recommended that from 400 to 800 gr. of an alkali (bicarbonate of soda) should be given daily to counteract the tendency to acid poisoning, and that the salicylate should not be given when the bowels are constipated or the kidneys are not acting freely. In a hospital, with resident physicians and nurses watching the patient day and night, such precautions may be carried out, but in private practice one does not want to run unnecessary risks, and the use of salicylate of soda in moderate doses calls for no such watching of the patient, and no such antidotes along with the drug.

Local Treatment.—As a rule the acute symptoms yield so readily to complete rest and salicylate treatment that local measures are now much less called for than formerly. When the joints are much inflamed and swollen and the fibrous aponeuroses generally are involved the sensitiveness of the patient may be so extreme that even the pressure of the bedclothes or a movement of the bed causes great suffering. It is advisable in such cases to have a long cage over the patient, protecting the trunk and limbs from any pressure. The swollen joints should be swathed in a thick roll of cotton-wool. If any one joint is specially painful, hot fomentations, sprinkled with laudanum or tincture of belladonna, may be applied at intervals. Blisters about the joint and local applications of salicylic compounds have been employed formerly, but are of little value as compared with the internal administration of salicylate of soda.

Serum Treatment.—Various efforts have been made to provide an efficient serum in this disease, but so far without much success. A serum has been prepared by Menzer, and he claims to have obtained better results from it than from any other form of treatment. So far his results have not been confirmed by others. Vaccine treatment has not led to any definite results, and this may be due primarily to the fact that the specific organism of rheumatic fever has not been discovered. While the *micrococcus rheumaticus* of Poynton and Paine may be the cause of the disease, it would appear to be an elusive type of organism which does not lend itself readily to the production of an effective therapeutic vaccine.

Complications.—In treating a case of rheumatic fever the physician always bears in mind the possibility of complications, and by far the most common and most important of these is inflammation of the heart. The carditis of rheumatism is, as a rule, an infection of the heart generally, but symptomatically the brunt of the infection may appear to fall on the pericardium, or the endocardium, or the myocardium. Whichever part may seem to be involved, and however slightly, it is a good rule to regard the case as one of cardiac infection, and therefore requiring more prolonged treatment than one in which the heart has escaped. The latency of cardiac disease must also be kept in mind, so that attention must be directed to the heart all through the convalescent stage, and even when the patient has been out of bed, in order to see how it responds to increased effort. More especially in the case of children are these precautions necessary, for it is in early life that the tendency to rheumatic heart disease is greatest. In the absence of well-marked evidences of cardiac involvement suspicion should always be aroused by a persistently rapid pulse, by cardiac dilatation, or by a faint mitral murmur.

If the heart is found to be involved the treatment must be carried out on general lines, for we have no means at present of directly treating acute carditis. The same measures are to be adopted whether the lesion is apparently endocardial or myocardial or pericardial. The great measure we have to fall back on is rest, perfect rest of mind and body, so that the circulation may go on in a steady uninterrupted manner, and the natural disappearance of the inflammation may take place under the most favourable conditions. The duration of the rest after an attack of rheumatic fever is to be regulated by the progress of the cardiac lesion. We naturally desire as regards the heart a *restitutio ad integrum*, and this will be manifested by a regular pulse of normal rate, an absence of dilatation, and the disappearance of endo- or peri-cardial murmurs. The time necessary may have to be counted by months rather than by weeks, and the process may be extremely tedious to the patient, but the important thing to realise is that at no time will the opportunity ever recur of treating the acute carditis and its effects successfully. We may not be able to secure complete healing, but we shall at least secure a minimum of permanent damage. Other measures tending to eliminate the poison should be persevered with, such as those acting on the skin, the bowels, and the kidneys. I do not know of any medicine which will affect the carditis. Digitalis is certainly useless in cases of recent inflammation of the heart and is probably harmful. Iodide of potash, and grey powder, in small doses, are still believed in as useful eliminants, and I

think may at times be useful. The pain of pericarditis may produce so much unrest in the patient that it must be relieved. For this purpose hot fomentations or leeches to the præcordium may prove helpful, but the free use of morphia is probably the most effective treatment.

A somewhat rare complication of rheumatic fever is hyperpyrexia, which is always serious, probably more from the intense toxæmia of which it is a sign than from the degree of fever. If the temperature rises above 106° F. an effort should be made to lower it by means of hot packs or packing ice round the patient. The general condition of the patient must be kept in mind and active measures directed to the hyperpyrexia should not entail great disturbance and exhaustion of the invalid. The administration of hot drinks and hot brandy and water are also useful, while antipyretic drugs probably do more harm than good.

The *convalescent stage* calls for some consideration. A liberal diet is to be allowed of nutritious and digestible foods. A fresh attack will often be induced by over-feeding, so that special attention should be paid to the condition of the digestive organs. If they are sound a mixed dietary of beef, mutton, fowl, fish, green vegetables, puddings and eggs may be allowed. Constipation must be avoided by the use of cascara or senna pods. A condition of anæmia usually follows an attack of rheumatic fever, whether cardiac disease has been present or not. It is not advisable to try to relieve this by large doses of iron, which will probably only have the effect of inducing a recurrence of indigestion and rheumatic pains. The anæmia will usually yield to the influence of diet, of green vegetables more especially, and of fresh air and sunlight.

A first attack of rheumatism, treated under favourable conditions, will usually be recovered from. In the case of adults there may be no further trouble, but in the case of children there is always a risk of recurrence, either in the form of a fresh attack of rheumatic fever, or in the more insidious form of rheumatic manifestations, such as tonsillitis, "growing pains," erythema, subcutaneous nodules, chorea, pericarditis or pleurisy. Any one of these forms may not be recognised as rheumatic and may escape treatment, with the result that fresh and progressive inflammation of the heart takes place. It is, therefore, a good plan after an attack of rheumatic fever in a young subject to continue the regular use of salicylate of soda for one or two years. The patient may be ordered to take at the beginning of each month 20–40 gr. of salicylate of soda daily for a week. By this means future trouble of a serious nature may often be avoided. G. A. S.

ANTHRAX, RABIES AND GLANDERS

Anthrax

The anthrax bacillus is not responsible at the present time for a large variety of lesions in this country, and these are limited almost entirely to the districts where trades in imported hides are carried on. By far the commonest lesion is the malignant pustule, or as it is more correctly termed, cutaneous anthrax. Other lesions are found in the lungs and intestine, but pulmonary and intestinal anthrax are very rare, and, as a rule, are not discovered until a post-mortem examination is made. If such are to be treated, an early recognition of the condition can only be made by a careful bacteriological investigation of the respective excreta in all cases of acute pulmonary and intestinal affections occurring in districts where there is a possibility of infection. In cutaneous anthrax the lesion is, as a rule, characteristic, but in all cases the diagnosis requires confirmation by the bacteriologist. In the treatment of cutaneous anthrax there are three methods suggested as being efficacious; the older methods of incision and simple cauterisation having been almost abandoned.

The methods are—

1. Expectant treatment.
2. Excision of the lesion.
3. Serum-therapy.

The two latter may be used in combination. Many observers hold that the expectant method alone is justifiable, and that a cure will result in the majority of cases. The statistics of all cases treated in this country contra-indicate the adoption of this plan.

In examining the records of all cases that have been dealt with in this country since 1905 it will be seen that excision of the lesion is the method of treatment which most often averts a fatal issue. In carrying out excision, it is essential that the whole of the lesion, together with a good surrounding margin, should be extirpated, and the resulting wound allowed to granulate up, with or without the application of nitric or pure carbolic acids or other caustics.

At the same time this method of treatment is not always the most convenient, for it so happens that the commonest site on the skin for the appearance of the lesion is on the face just below the margin of the orbit, a situation where it is not always possible efficiently to carry out complete excision.

Moreover, it is apt to produce so severe a scar that such conditions as ectropion are liable to follow the healing of the wound, and to produce marked disfigurement. The period of convalescence demanded by such a method of

healing has, moreover, to be considered, since it is among the working-classes that infection takes place.

Serum-therapy has to a large extent replaced the above methods. The type of serum used is that introduced by Sclavo, which was first brought into this country by Legge. The method consists in the injection of large doses into the subcutaneous tissues, the smallest initial dose being no less than 40 c.c. If the first dose does not bring about the desired result, injections of 20 c.c. may have to be repeated daily.

The immediate effects of the treatment are variable, both on the general condition of the patient and on the local lesion. Sometimes there is no obvious change, at others the temperature rises within the next twenty-four hours to 103–105°, and occasionally a rigor follows. Headache, malaise and nausea are common sequels.

The lesion may remain as before, or there may be a considerable increase in the area of inflammation around the local focus. Both of these effects, however, clear up with forty-eight hours, ofttimes sooner, and the patient speedily becomes convalescent. Anthrax bacilli almost always disappear from the lesion within eighteen to forty-eight hours. Statistics show that if the condition is diagnosed early this treatment is as efficacious as excision; and it has the advantage that there is usually very little scarring and no large granulating surface from which secondary septic infections may result.

Again the period of isolation is considerably diminished, as the patient may return to his work within a few days, instead of weeks, since he is no longer infectious.

A combination of the use of serum therapy with excision is advisable in the more severe lesions. Serum therapy is the only possible method of treatment for the pulmonary and intestinal types of the disease when diagnosed.

No harm has so far been observed in the use of the serum, and it has even been given intravenously together with normal saline solution without harmful effect. As to prophylaxis, all bedding, bed-clothes, towels, etc., should be burned, since the disease is spread by the spores of the bacillus. All feeding utensils and the like should be specially sterilised by prolonged heat at high temperatures; touching of the lesions with the fingers should never be allowed.

Rabies

Hydrophobia is a disease which has become almost extinct in this country. Isolated cases, however, are met with from time to time.

Its treatment comprises prophylaxis and active treatment. The former method consists in immediate attention to a bite produced by a suspected animal. The wound, if possible, should be excised completely, and combined with the application of the thermo-cautery, pure carbolic acid, nitric acid or silver nitrate.

As a rule there is no advantage in doing this if the lesion has been present for some time, as the toxin spreads up the nerve sheaths to the central nervous system. During the incubation period, which varies from five days to six months, the average period being about forty days, some method of immunisation should be adopted.

The Pasteur method of immunisation is the favourite one. This consists in the introduction of a vaccine in daily doses subcutaneously. The vaccine is prepared from the dried spinal cords of rabbits which have been infected with the virus, starting with attenuated virus obtained by drying for a period of fourteen days; and each successive dose being obtained from cords dried a shorter period is of increased potency. The highest strength is, as a rule, prepared from a cord dried for three days. The process of inoculation lasts for fourteen days. An intensive method is also used in which the process is carried out in eight days, a toxin of greater potency being employed for the first dose.

By the use of this method the death-rate has been reduced from 10 to 1 per cent. For success it must be adopted at the earliest possible stage.

Serum therapy has also been advocated by Tizzoni, and it is alleged that cures take place even after the symptoms of the disease have appeared. This serum is prepared by immunising sheep with the attenuated virus. The virus is attenuated by the Italian method of treating the infected rabbits' cords with gastric juice. The dosage of the serum is 10, 5, 5 c.c., given on three successive days.

More recently Marie has succeeded in producing a sensitised vaccine, *i. e.* the emulsion of the infected rabbit's cord is mixed with antirabic serum, the latter being removed by washing with normal saline solution after they have been in contact for twenty-four hours. It has the advantage of producing immunity more rapidly than the method used by Pasteur.

Glanders

The infections due to the Bacillus Mallei are fortunately rarely seen among human beings. Stablemen and persons dealing with infected horses or other animals, and pathological investigators are most liable. The result is almost invariably fatal in acute cases, but in the more chronic forms a certain number recover. The treatment consists in the giving of stimulants liberally, and the use of certain drugs such as iodine, arsenic or creosote.

In the pulmonary and intestinal types little can be done locally. An attempt should be made to disinfect the initial site of infection. When this occurs in the nasal mucosa, washes should be frequently given with the application of caustics to any ulcers that may manifest themselves.

If the focus is in the skin, abscesses should be opened, nodes or ulcers excised, disinfectants such as the mercury salts or zinc chloride applied, or the actual cautery used. No anti-serum has yet been prepared, but vaccine therapy has been adopted, though with little success.

Great care should be taken in isolating an infected patient, as dissemination from one individual to another readily occurs. The same care should be adopted in identifying and killing the infecting animal, and the stables should be submitted to a very thorough process of disinfection. W. G. B.

TETANUS

1. **Prophylactic Treatment.**—In the great majority of cases, tetanus is caused by an earth-infected wound, and burns appear to be particularly liable to give rise to it, at any rate in America. Great care should be taken, therefore, to cleanse thoroughly any such wound. Unfortunately this is not a certain protection. In several cases in a series recently studied by the writer, tetanus supervened in spite of careful cleansing and the use of antiseptics. It is probably wise to employ Lister's "strong lotion" (carbolic acid 1 in 20 + solution of $HgCl_2$ 1 in 500), for dirty wounds. Even this will not kill tetanus spores in a short time, but if the other germs are killed tetanus bacilli do not usually produce any symptoms.

It has been advised to inject a prophylactic dose of antitetanic serum whenever one has to deal with an earth-infected wound. This advice appears to be sound, for in animals protection can usually be obtained in this way. The results of giving the serum *before* symptoms appear are far better than when the patient is already in convulsions. Nevertheless, there are about twenty cases on record in which tetanus has supervened in spite of the prophylactic injection. The writer has seen one case in which the serum itself produced symptoms exactly like tetanus within twenty-four hours, but the patient recovered. Apparently most of the individuals who developed the disease notwithstanding a precautionary dose of serum have recovered (six out of eight recorded).

It must never be forgotten that the bacilli may be introduced during surgical operations by infected instruments or catgut. The only safety lies in boiling for more than fifteen minutes; nothing less than this can be relied upon to kill tetanus spores. Iodine catgut is safe. The theory has recently been advanced that post-operative tetanus is due to an infection from the alimentary canal.

A remarkable means by which the disease may be lighted up into activity is by the intramuscular injection of quinine. It has long been known that tetanus may follow this treatment, and the sterility of the needle was suspected, but it is now shown that lurking bacilli, unable to produce symptoms because unaccompanied by cocci, may have virulence conferred upon them after the quinine injection. This has been verified in animals. Quinine ought, therefore, only to be given by the mouth except in cases of urgency.

When the symptoms of tetanus have already manifested themselves, the prognosis depends more upon the nature of the infection than upon the mode of treatment adopted. In acute cases the mortality is about 83 per cent., in milder or chronic cases about 43·6 per cent. (Jacobson). Of thirty-one cases at the Bristol Royal Infirmary nine recovered, but in three or four of these there was no wound discovered. The more difficult it is to find a cause, the better the outlook. In our cases, the leg and foot wounds gave a better prognosis than those of the arm, and all the head cases died; tetanus toxin travels by the nerves, so that the longer the nervous route the better the prognosis. The incubation period gives some clue to the result; of patients whose symptoms arose in ten days or less, only one out of twelve recovered, but of eleven cases with a longer incubation period four got well. It has been known from the time of Hippocrates that if a patient survives the fifth day of symptoms he has at least an even chance of recovery, and our figures bore this out. In appraising the value of the treatment adopted in reported cures of tetanus, the incubation period is very important; when it is long the patient would probably have recovered anyhow.

2. **Treatment of Declared Tetanus.**—Three cardinal principles have to be observed, to remove the focus whence the toxin is absorbed, to combat the infection of the nerve cells, and to relieve the symptoms.

(a) *Removal of the Affected Area.*—If there is an obvious wound, which will probably be quietly suppurating, it should be cut out *en masse* under an anæsthetic, or burnt out thoroughly with the cautery, without loss of time. It is no use trifling with antiseptics, which will not kill the spores unless used as caustics.

(b) *Antagonising the Infection of Nerve Cells.*—The majority of surgeons have come to the conclusion that antitetanic serum given by the

ordinary means and in the ordinary doses has been tried and found wanting. Even in experimental animals it meets with little success after symptoms have developed. Although antitoxin is able to neutralise tetanus toxin, it has but little if any power to disrupt the union between the toxin and the protoplasm of nerve cells.

Nevertheless, it is customary to inject 20 to 30 c.c. daily into the subcutaneous tissues of the abdomen, in the hope that further infection may be averted. The injection is made with an antitoxin syringe which has been boiled, the skin being prepared by painting with tincture of iodine or other suitable method. The puncture is sealed with collodion. Septic complications are very uncommon, but it is well to cover with an aseptic dressing for a day or two.

Attempts have been made to obtain better results by greatly increasing the dose of the serum. In a small series of twenty American cases treated with injections of 500 c.c., it is claimed that as many as 75 per cent. of the patients have been saved, but they appear to have had a mild type of the disease. Still, large doses are worth a trial, and the writer has seen one quite severe case saved by this treatment combined with the injection of magnesium sulphate. The large doses are quite harmless.

Another device which has been recommended is to give the antitoxin into the brain, or vertebral canal. In the former method of treatment, a trephine hole is made over the frontal lobe and the needle plunged into the cerebral substance. This procedure has been followed by abscess of the brain, and is not likely to come into favour. It is claimed by some American writers, notably by Rogers, that better results are obtained by injecting the serum through a lumbar puncture into the spinal theca amongst the nerves of the cauda equina. Seven cases are quoted, of whom four recovered, in which Rogers gave 10 to 20 c.c. subcutaneously, with the same dose intravenously, 5 to 20 minims into the great nerve trunks, and 10 to 20 c.c. into the cauda equina, deliberately aiming at penetrating the nerves. One would wish to be very sure that the antitoxic serum was aseptic before running this risk, or the patient's slender chance of recovery might be further jeopardised by meningitis.

Baccelli's Phenol Injections.—If statistics could be relied upon, infinitely the best results have been obtained by this method. In Italy it appears to be the routine treatment. Baccelli reports ninety-four "severe" cases, of whom only two died, and another series of thirty-eight "very severe" cases, of which sixteen died. But these figures are collected from published cases, which is misleading, as it is only the successes that are likely to get into print. The method has been tried two or three times at the Bristol Royal Infirmary without success, but it is simple and harmless, and might well be used as a routine. It appears to have saved some quite severe cases.

Hypodermic injections of a 3 per cent. solution are given every two or three hours. The initial doses contain about 3 gr. of phenol, and it is aimed to get in as much as 30–45 gr. in twenty-four hours. Carboluria will probably occur, but may be neglected.

The theory is, of course, that the bacilli are killed by the carbolic acid, but this is open to doubt, and the sedative action probably helps.

The Russian Method.—Krokiewicz, acting on the principle that tetanus toxin has an affinity for nervous matter, seeks to divert part of its activity by giving injections into the subcutaneous tissues of sheep's brain. This is made up into an emulsion with normal saline, 10 gr. being given in 30 c.c. of saline (150 gr. in 1 oz.) every other day. Of sixteen cases, eight being described as severe, thirteen are reported to have recovered.

(c) *Symptomatic Treatment. Intraspinal Injection of Magnesium Sulphate.*—Meltzer observed that in experimental animals magnesium salts would inhibit spasms of spinal origin, and for this reason he introduced the method into therapeutics. It is usual to give 3 c.c. of a 25 per cent. boiled solution of magnesium sulphate by injection into the vertebral canal in the lower lumbar region. Probably smaller doses would serve the purpose. The injection is repeated every day. There is often produced a very high tension of cerebro-spinal fluid in consequence of the osmotic pressure of the salt, and in that case it is probably wise to let some drain away at the second and third puncture. The patient's head must be kept raised.

We have no large or reliable body of statistics to guide us in appraising this method, and at the best it is only symptomatic, but the personal impressions of a number of British and American surgeons are rather favourable. The writer believes that he has seen it do good. Phillips records four recoveries in his seven cases, and collects from the literature twenty-eight cases, of which sixteen recovered. The method is not altogether free from risk; one fatal case is recorded and in another artificial respiration was necessary; bronchorrhœa may follow.

Sedatives.—All the sedative drugs have been tried in the treatment of tetanus, and they probably allay the pain even if they do not control the spasms. In the Franco-German War the German surgeons considered that curare gave the best results, but it is seldom used now. Morphine relieves the pain, but does not

check the spasms, and usually fails to induce sleep. Chloral and bromides probably give better results. When swallowing is difficult, they should be given in full doses per rectum. Inhalation of chloroform may be desirable when the convulsive attacks are long and severe; it will control them for the time being, but should not be kept up for longer than half an hour once or twice a day.

The **general management** of a case of tetanus calls for a few remarks. The patient should be isolated in a quiet darkened room with as little coming and going as possible. The bowels, which are often very confined, may be kept open once in two or three days with drop doses of croton oil, but calomel, 5 gr. at a time, should be tried first. If swallowing becomes difficult, fluids may be given with a feeding-cup, or if necessary a rubber tube may be passed down the throat through a gap in the teeth. If passing it causes spasms it may be left *in situ*.

Some Italian authors believe that hot bathing is a valuable means of allaying the spasms.

3. **General Summary.**—In the writer's opinion the measures to be taken are as follows—

A prophylactic dose of antitoxin (20 to 30 c.c.) should be given when there is an earth-infected wound, at any rate in countries where tetanus is common. Thorough cleansing with "strong lotion" should be used at once.

In mild cases of tetanus, with an incubation period of a fortnight or more or with no obvious wound, in which the spasms are infrequent and not severe, give sedatives, and 30 c.c. of antitoxin subcutaneously, repeated if the spasms recur. Isolate the patient. Even if it is probable that recovery will take place it is wise to give antitetanic serum in all but the mildest cases showing only trismus but no wound and no spasms, because sometimes symptoms which begin mildly pass into fatal manifestations of the disease later on. The wound, if any, should be excised or thoroughly cleaned up with strong antiseptics.

In severe cases, the patient ought to be isolated, the wound excised, and sedatives administered. If an antitoxic serum of guaranteed sterility can be obtained, inject 10 c.c. into the spinal theca by lumbar puncture, or 20 c.c. intravenously by means of a needle and funnel into the median basilic or other prominent vein. Sterilise the skin with tincture of iodine or spirit and biniodide, and make the vein prominent by tying a bandage round above it. Take care to inject no air bubbles, and remove the bandage when the needle is safely inside the vein. The serum may be diluted with 50 c.c. of warm saline. Unfortunately one cannot safely inject large doses of the albumins of blood of another species.

Further, the patient should be given 300 to 500 c.c. of antitoxin subcutaneously, in two or three places, by means of needles and a funnel.

If there are severe spasms, Meltzer's magnesium sulphate ought to be given by lumbar puncture.

In the absence of antitetanic serum, in cases where it cannot be afforded, or when it has been given as above described on the first day, and there is no marked improvement, Baccelli's carbolic acid injections ought to be given a trial, because although the statistical evidence is so compiled as to be unduly favourable, the method has undoubtedly cured some quite severe cases after antitoxin had failed to effect any improvement.

GONOCOCCAL INFECTIONS

Abortive Treatment.—The abortive treatment should only be attempted if the patient comes for advice within four days after contracting the disease, and provided the subjective symptoms are slight only. The treatment should consist in washing out the anterior part of the urethra twice a day with about a pint of a 5 per cent. solution of protargol, or a 25 per cent. solution of argyrol, or a 1 per cent. solution of hegonon. The treatment should not be continued for more than three days, and if it has been successful no gonococci should be present on the fourth day.

Unfortunately patients seldom come for advice soon enough, but if a case can be obtained before the discharge is copious or the patient has a burning pain on passing water the abortive treatment will almost invariably prove successful. Putting the patient to bed during the course will materially assist the treatment.

Practical Differences between Anterior and Posterior Urethritis

The great difference between acute anterior and posterior urethritis rests in the fact that, owing to the collection of pus in the prostatic portion of the urethra and its passage along the path of least resistance, which is over the neck of the bladder into the bladder itself, so much irritation is set up, that in acute posterior urethritis the patient is always requiring to pass water, and has to get up three or four times or more in the night to do so.

If the two-glass test is used, owing to the pus mixing with the urine in the bladder both portions will be thick. If the pus collects in the urethra only, then the urine passed in the first glass will be thick, while that passed in the second glass will be clear.

If both portions are thick and the patient does not have to get up in the night to micturate, the thickness is either due to phosphates or urates: the former will disappear on adding acetic acid and the latter on heating.

The two-glass test is not of much use in chronic cases, because in whichever part of the urethra the lesion is situated the threads brushed away therefrom will only appear in the first glass. If threads are seen in the second glass, they usually come from the prostate.

Speaking generally, long threads are urethral, short threads and dots are prostatic. A urethroscopic examination will show in which part of the urethra there is inflammation.

Treatment of Acute Urethritis

1. **Hygienic.**—First of all rest, both to the part—by wearing a suspensory bandage—and to the person. Bed is seldom necessary, but active exercise must be forbidden. Alcohol should be strictly avoided, and hot foods and condiments—mustard, pepper, sauces, etc.—should not be taken. Excessive smoking has not infrequently aggravated the disease.

2. **Symptomatic.**—Pain on passing water can generally be diminished by diluting the urine by drinking more milk and water, or barley water and alkaline mineral waters, Evian water in particular. Decreasing the acidity of the urine by drinking lime water often affords relief. For the acute pain caused by spasm of the compressor urethræ muscle, nothing is better than a warm hip bath or a hot opiate fomentation, which at the same time relieves the retention, if present. If there is hæmaturia the patient should remain in bed until hæmorrhage has stopped, and cold evaporating lotions should be applied to the penis, and sodium salicylate given internally.

3. **Local.**—Two courses are open: giving by the mouth such drugs as are excreted through the urethra and direct application of drugs to the urethra itself. The drugs usually given internally are resins and balsams like cubebs, copaiba, sandal-wood oil, etc., the last being the best; but all are of very little value and less useful than the well-known mistura alba, which keeps the bowels well open—a most important point in the treatment of gonorrhœa. In acute posterior urethritis nothing is better than sodium salicylate.

A mixture which finds favour with some is the following—

℞ Copaibæ ♏ xv
Pulv. Cubebæ gr. xxx
Pot. Iod. (in increasing doses) beginning gr. x
Sp. Ætheris Nitrosi ♏ xv
Mucilag. Acaciæ ʒ i
Infus. Taraxaci vel. Buchu ad ℥i.

When this mixture is given, twice daily injections of a 1 in 10–20 solution of perhydrol (Merck) should be ordered. The theory is that the H_2O_2 liberates the iodine from the potassium iodide, and allows the free iodine to exert its destructive action upon the gonococci.

The local application of the proprietary preparation known as "Iodex" is now under trial, and would appear to give favourable results. For direct application to the urethra, potassium permanganate 1 in 4000 or until the solution is the colour of red blotting paper is the best drug. If a silver salt is desired, preference should be given to a 0·1–0·3 per cent. solution of hegonon. It should always be remembered that every salt of silver should be freshly prepared, and that whatever drug is employed more harm can be done by using too strong than too weak a solution.

No injections should be given until the pain on micturition as well as all redness and œdema of the penis have disappeared. They should then be employed twice daily until every trace of the discharge has ceased, and for at least ten days after. In quite a large number of cases this will result in cure. The old fear of driving the disease back by using injections is not supported by practical experience. In anterior urethritis the solution injected goes only as far back as the triangular ligament and returns through the meatus.

Acute Posterior Urethritis.—In order to wash out the whole of the urethra and bladder, which is necessary in acute posterior urethritis, either the column of fluid to be injected must be raised higher, or the return opening in the glass tube must be stopped up. It is far better to wash out the urethra and bladder with a cannula just inserted into the meatal orifice, than by passing an instrument directly into the bladder, because it is so easy to injure an inflamed mucous membrane, and through the abrasion so caused, the gonococci may reach the systemic circulation.

Chronic Urethritis.—The anterior part of the urethra is rarely affected alone; when such is the case, twice daily injections of a 0·1–0·3 per cent. solution of albargin will speedily effect a cure; if it does not, then the presence of a para-urethral canal must be considered. These canals may or may not communicate with the urethra internally, but they usually open externally in the region of the corona glandis

or in the glans penis just external to the meatal orifice. They may be unilateral or bilateral, and are usually about 3 cm. or more in length. They can only be closed by electrolysis, which is accomplished by inserting a fine platinum needle attached to the negative pole, and passing a current through it of 1–2 ma., for one to two minutes.

Another cause of chronic or recurring anterior urethritis is inflammation of the bulbo-urethral glands. The secretion should be expressed by massage and then an injection of a 0·5 per cent. solution of silver nitrate given per urethram. A chronic or recurring urethritis is most commonly posterior and dependent upon either inflammation of the prostate or the seminal vesicles. Massage per rectum of these structures, continued with instillations per urethram by means of an Ultzmann's syringe of 1 or 2 c.c. of a 0·5 per cent. of silver nitrate, or 5 per cent. solution of copper sulphate will sometimes result in a cure. It must be remembered that the mere presence of threads in the urine does not always signify an active or even latent gonococcal infection, because many patients who have had frequent attacks or who have been treated with too strong solutions may have threads in the urine for the remainder of their days. A cure cannot be ascertained by searching for gonococci, since in many cases a chronic urethritis may be kept up by the diphtheroids, staphylococci and streptococci, which have long since exterminated the gonococci. These secondarily infected cases are usually made worse by the injection of fluids which have a specific anti-gonococcal action, and only clear up when the silver salts are supplanted by very weak solutions of biniodide or perchloride of mercury. The best method of diagnosing a chronic gonococcal urethritis is to give a large dose of a potent gonococcal vaccine, and if there are gonococci latent, the injection will quickly stir them up, with the result that within forty-eight hours the patient will either have had an increase in the urethral secretion on rising or even a profuse discharge. The further administration of vaccines may cure such a case, especially if the prostate or the seminal vesicles are affected. Many a case of urethritis is kept up by a stricture, and no treatment short of gradual dilatation or urethrotomy will effect a cure.

Gonococcal abscesses along the penis should be treated as long as possible with cold evaporating lotions and rest; the knife should only be used when they actually point, and then only the smallest incision should be made just sufficient to let out the pus. A urinary fistula may result, but it will almost invariably close of its own accord in time, and operative interference is seldom called for.

Many a case of acute prostatis will resolve by merely putting the patient to bed and inserting a psychophore per rectum, through which runs a stream of cold water. A prostatic abscess frequently bursts into the urethra and brings about a spontaneous cure; if it points into the rectum, only a tiny incision should be made to evacuate the pus. Resolution is rapid and a fistula is extremely rare.

Gonococcal Cystitis so rarely occurs, and when it does the infection becomes so quickly superseded by the bacillus coli that the treatment does not differ from that which is described elsewhere.

Epididymitis, on the other hand, is an extremely common complication, and, as when bilateral it is a frequent cause of sterility, may call for special and energetic treatment. Some few cases will resolve under rest in bed and local applications of Lotio Plumbi or Ichthyol, with sodium salicylate internally, but if a case is seen early it is better to employ either of the following two methods of treatment—preferably the former.

1. Take the scrotum into one hand, make the skin tense over the epididymis and plunge a scalpel into its substance, in its long axis, in two or three places; the pain is momentary, but the relief which so quickly sets in is enormous. Then treat in the usual way with lotions, etc.

2. Inject into the epididymis 1–2 c.c. of electrargol. The epididymis reaches its normal size in one to three days, and only occasionally is a second injection necessary.

Paraphimosis occurs mechanically and is not due to the patient having drawn back his foreskin and being afterwards unable to draw it forwards again. Attempts at reposition frequently fail, then the treatment is either to divide the constricting band or better to remove the incarcerated portion of skin and stitch the edges together. If necrosis has already occurred the less done the better; the parts should be kept clean with antiseptic lotions and powders should be freely used to keep the necrosed area as dry as possible, leaving the rest to nature.

Systemic Complications.—The commonest are iritis and arthritis, and it is in such conditions that vaccines are most useful, but local treatment should never be omitted, and special attention should be paid to the genital tract. In the case of iritis, atropine should be used, in the case of arthritis, sodium salicylate with potassium iodide should be given internally, and a 10 to 40 per cent. guaiacol ointment should be applied externally. Atophan is sometimes very useful and can be prescribed as follows—

℞ Atophan
Sod. Bicarb. āā gr. vii
M. f. pulv. in cachet.

One cachet to be taken before every meal.

The addition of guaiacol carbonate may be helpful.

Venereal Warts, gonorrhœal warts or condylomata acuminata, are hypertrophic masses of epithelium produced by inflammation in the corium. The inflammation is not caused by the gonococcus, but by the bacterial flora which collects and flourishes in the corona glandis. Keeping the area perfectly dry with powders will often result in their spontaneous disappearance; this is the best treatment when there are many. If there are only a few, it is best to scrape them away with a Volkmann's spoon and to paint the base with silver nitrate stick, which both sterilises the surface and stops the bleeding.

Gonorrhœal Ophthalmia.—(1.) *Infantile.*—Prophylaxis is the chief point, and that can only be effected by keeping the mother's genitals as clean as possible, and by bathing the baby's eyes immediately after birth with a 2 per cent. solution of silver nitrate, or a 10 per cent. solution of argyrol. It is well to wash out the silver solution by some normal saline.

(2). *Adult.*—The affected eye must be protected at once with a Buller's shield, which is an ordinary watch glass retained in position by a piece of adhesive plaster. The eye should be frequently washed with a solution of a silver salt, atropine drops must be used to prevent adhesion of the iris, and leeches applied to the temple to reduce inflammation.

Vaccines.—A vaccine to be potent must be prepared, without the employment of heat, from a fresh culture, or the first sub-culture which has not been allowed to grow for more than forty-eight hours. The vaccine should be fresh, as it begins to deteriorate after the tenth day, even when kept in the dark at 0° C. No evidence is forthcoming that an autogenous vaccine is to be preferred to a heterogeneous. There are three different methods of employing vaccines: (1) Ordinary vaccine given subcutaneously or intramuscularly; (2) autolysed vaccine given intravenously; (3) sensitised vaccine given subcutaneously or intramuscularly. Of these three the last is the best, because, provided the immune serum used for sensitisation contains anti-endotoxine, no negative phase follows its employment and the patient does not suffer from toxic symptoms (for full details see *Journ. Path. and Bact.*, 1913, Vol. XVII. 559).

Ordinary Vaccine.—The initial dose should not exceed 5 million, and the second dose of the same size should not be given for ten days or more; and each subsequent injection of very gradually increasing doses should not be given more than every seven or ten days.

Intravenous Autolysed Vaccine.—The therapeutic effect is better than that obtained by the preceding method, but as many injections are required, toxic symptoms may often occur. The initial dose should be 1 to 3 million given in 5 oz. of saline; the succeeding doses should gradually be increased up to 15 million, and not given oftener than once a week.

Sensitised Vaccines.—Injections should be given on three successive days in doses of 20, 50 and 100 million. If the patient has no reaction, doses of 200, 500 and 1000 million may be prescribed on the fourth, fifth and sixth days. Should a reaction appear after any one of these, fourteen to twenty-one days should elapse before a further series are given.

The sensitised vaccines are most useful in acute cases treated early, and speedily effect a cure. Chronic cases may often be improved enormously by vaccines, but after they are stopped the disease remains latent for a time, only to break out again; therefore a cure should not be guaranteed.

In cases of arthritis where there is much fluid in the joint, tapping is often necessary, after which a Martin's bandage should be applied to prevent refilling. Injecting the fluid drawn off subcutaneously has often been advised, but it seldom does much good. (For further details see article on *Chronic Diseases of Joints.*)

Autogenous vaccines made from the organisms which have been grown from the expressed secretion from the prostate, which contain staphylococci, streptococci and diphtheroids, may occasionally be beneficial when the gonococcal vaccines have failed.

Vaccines in Women and Children.—Although vaccines will frequently banish the symptoms of a cervicitis and endometritis they will not cure the case, unless local treatment is also prescribed. The pains which salpingitis produces will likewise disappear under vaccine treatment, but the majority of cases recur in time. Gonococcal joint affections, which are commoner in women than is suspected, yield very well to vaccines.

Women always seem to be more affected by vaccines than men, and owing to the marked reaction which may occur in them after gonococcal vaccines, namely, increase of pains, menorrhagia and metorrhagia, it is advisable to use sensitised vaccines.

Children.—Joint affections respond admirably to vaccines, but the vulvovaginitis which is always the first symptom, and by far the most troublesome, is in the majority of cases quite uninfluenced. Vaccines should therefore only be tried in obstinate cases as an adjunct to systematic local treatment.

CHOLERA

The essential principles in the treatment of Asiatic Cholera are: (1) to replace as soon as

possible the fluid and salts lost from the blood through the copious evacuations, so as fully to restore the circulation and the renal functions, thus producing an excretion of the toxins already absorbed; (2) to destroy the poisons formed in the bowel, thus cutting short the disease.

Estimations should be made of the specific gravity of the blood and of blood pressure to reveal the amount of fluid lost from the system and the degree of collapse. The former can most conveniently be found by means of series of small bottles of glycerine and water from 1,042, 1,044, etc., up to 1,070, which can be made up with the help of an accurate hydrometer. The bottle in which a small drop of the finger blood just floats for a second or two has the specific gravity of the blood, or if it sinks in 1,064, but rises in 1,066, then the intermediate figure is the correct one. The rectal as well as the surface temperature should also be taken on admission.

Methods of Replacing the Lost Fluid.—In the first place water and barley water should be given freely by the mouth in small quantities at a time, vomiting not being a contra-indication, as some toxins are thus removed. Half a pint of normal saline (90 gr. of sodium chloride in a pint) should be given by the bowel every two hours, and in mild cases this may suffice to prevent collapse and save the necessity of more active measures. Saline has also been very largely given subcutaneously in cholera, but this is far inferior to the intravenous method, as it is painful and tedious to run sufficient quantities into the connective tissues. When used in the acute stage they should be hypertonic, as explained below. In an adult, up to three pints of sterile hypertonic saline can be rapidly given intraperitoneally by means of a special canula made for me by Down Bros., or by a small trocar and canula as successfully used by Bishop. This method is also inferior to the intravenous one, but as it is simpler and more rapid it may be valuable when the circumstances or the number of cases prohibit the use of intravenous injections. Lastly, we have the intravenous method by means of a canula tied into a vein at the elbow, or in small children over the internal malleolus. The vessel is fully exposed and incised transversely below, a forceps holding the anterior wall, so as to form a small flap, beneath which the canula is readily passed and tied into the vein, the distal portion of which has first been ligatured. The most convenient canula is a stop-cock one, with the end tapering slightly towards the point so as to enter a small vessel easily. In very young children a finer canula can be made by melting and drawing out the end of a small piece of glass tubing, while I have found that even puny infants can be transfused through the great saphenous vein at the ankle with the physiologist's fine glass canula for blood-pressure work. By using a glass bulb graduated in ounces the rate at which the fluid is entering the vein can be timed and regulated by means of the stop-cock.

When collapse is present in an adult three to four pints should be run in at the rate of a pint in five minutes, or four ounces per minute, to obtain a full pulse. When the specific gravity was originally 1,065 or over, an additional pint or two may be injected at the rate of one ounce per minute, if severe headache or oppression in the chest does not result, and if the patient is quiet and evidently relieved. In children of ten about one and a half pints may be given, less for younger subjects.

The Indications for an Intravenous Injection are: (1) If the pulse is very feeble at the wrist, the blood pressure below 80 mm., and the specific gravity over the normal figure of 1,056 to 1,058. (2) Whenever the specific gravity is raised to 1,063 or over (which means that at least three pints of fluid have been lost to the system), even if the blood pressure is over 80 mm., in order to anticipate and prevent the threatened collapse. (3) In the absence of the above guides severe cramps, restlessness, cold and blue extremities are in themselves safe indications for intravenous injections in cholera.

The *solution* should be hypertonic, containing 120 gr. of sodium chloride, 6 gr. of potassium chloride and 4 gr. of calcium chloride to a pint, soloids (B. W. & Co.) containing these proportions being on the market, four of which in a pint make the hypertonic solution and three an isotonic one. The *temperature* of the fluid, which must have been completely sterilised by boiling, should depend on the rectal temperature of the patient, and unless this is subnormal, as in a few very severe cases, it should not be above blood heat. If the rectal temperature is over 100° F. the saline should be injected at several degrees below blood heat, while if the rectal temperature is as high as 102°, I give the saline at the room temperature of the Calcutta hot and rainy seasons, namely from 80 to 85° F. I have in this way successfully transfused patients with a rectal temperature as high as 105 and 106°, who would certainly have died of hyperpyrexia without this precaution. If collapse again ensues, or the specific gravity of the blood rises to 1,063 or over, the hypertonic intravenous injection must be repeated, and in occasional cases even a third or fourth injection may be successful.

Destruction of Cholera Toxins in the Bowel by Permanganates.—I have shown by experiment that permanganates have the power of rapidly oxidising cholera toxins into harmless bodies,

while the small bowel is so empty in this disease that the drug can be given in sufficient quantities by the mouth in the form of keratin or salol coated pills to affect the course and mortality of the disease materially. In severe cases two pills, each containing 2 gr. of potassium permanganate, are given every quarter of an hour for two to four hours, and then every half hour until the stools become less copious and of a greenish or yellow colour. In milder cases and in children smaller quantities are given. In addition, a solution of calcium permanganate, of a strength of from 2–6 gr. to a pint is given to drink in large quantities. Commonly, in about six to eight hours the stools change colour, when the permanganates are omitted, but a further course of 16 gr. is given twenty-four hours after admission to guard against relapses, or whenever rice-water stools are again passed.

The Reaction or Febrile Stage of Cholera.—When the circulation of a cholera patient revives, either naturally or after an intravenous saline, the temperature rises usually to 102 or 104° F. This reaction must be carefully watched, and if the fever exceeds 104°, ice to the head, cold sponging and cold water enemata must be used immediately, for if the patient once becomes unconscious from hyperpyrexia I have never seen recovery take place, although a temperature of 106° is harmless if detected and reduced without delay. Restlessness and delirium after a transfusion are signs of dangerously high fever. Excessive reaction is most common in Europeans during very hot weather.

In the collapse stage of cholera no drugs except permanganates are of any use, as absorption is completely at a standstill. Opium in any form I have found to increase the mortality greatly, especially from uræmia, and I never allow it to be given in any patient whom I even suspect to be suffering from cholera. *Acids* were once largely used, but completely failed in the Hamburg outbreak, and I have also found them to increase the mortality. Intestinal disinfectants designed to kill the cholera organisms in the bowel have also signally failed. *Astringents* are not only useless but increase the danger of uræmia, and I never try to check the diarrhœa by their means, especially as I find that as soon as the renal secretion becomes free (say 2 pints in twenty-four hours), and the rectal salines can be safely omitted, the evacuations stop spontaneously. *Ammonia* in the form of sal volatile and ammonium carbonate is the best stimulant, being sometimes useful in the later stages, especially if there is any congestion of the lungs. *Alcohol* is injurious, increasing the vasomotor paralysis, and I never give it except to convalescents accustomed to its daily use, when champagne is the best form.

The Treatment of Deficient Renal Excretion.—By far the most difficult condition to deal with is the failure of the kidneys to resume their functions during the stage of reaction, as is common in patients in whom there has been persistent renal stasis during prolonged collapse before treatment began. In the first place the deficiency may be due to a continued high specific gravity of the blood, such as from 1,058 to 1,064, leaving too little fluid for the kidneys to act on. This is usually easily remedied by subcutaneous, or better slow intravenous, injections of 1 or 2 pints of normal saline (90 gr. of sodium chloride to a pint), which often suffices to increase the urinary excretion at once. Secondly, it may be due to continued low blood pressure, from vasomotor paralysis. This is a more serious condition, since in an adult male a pressure permanently much below 100 mm. nearly always results in fatal suppression of urine, especially after middle life. Salines may still be given cautiously if the specific gravity is not down to 1,050 or less, but vaso-constrictors and cardiac stimulants are of equal importance. Of the former adrenalin is sometimes useful at first, but pituitrin is more valuable on account of its prolonged steady action. In addition digitalis, or better strophanthin, which is said to dilate the renal vessels, and caffein-sodio-salicylate should be persisted with, while oxygen inhalations are worthy of trial. As the alkalinity of the blood is much reduced in the uræmic stage of cholera I have for some time given full doses of potassium citrate after the collapse stage is passed, with, I think, beneficial effect. Hot-air baths I have found to be too exhausting. All the above measures too often fail, and the greatest safeguard against the deadly uræmic complication is early and repeated intravenous salines to shorten the collapse stage with its dangerous renal stasis, which no doubt markedly damages the kidney epithelium. With previous organic disease of the kidney the chances of recovery are greatly reduced.

Diet.—The most essential point in diet is to avoid giving any form of animal albumen, from which toxins can be readily elaborated by the comma bacillus, during the first three days. Water and barley water only are allowed *ad libitum*. In favourable cases late on the third day a little arrowroot and whey may be cautiously tried, though relapses occasionally occur, which are usually recovered from on reverting to the former treatment. Next, citrated milk is allowed and the diet gradually increased. The patient must be kept recumbent, as late fatal syncope is not unknown.

The system of treatment which has been briefly outlined has reduced the death-rate from cholera in Calcutta and elsewhere to

considerably under one half of its former rate, and it is now rare to lose a previously healthy subject who comes under treatment during the first six hours of the attack. L. R.

TUBERCULOSIS

In following the progress of a parasitic disease, such as tuberculosis, we are watching a life-and-death struggle between two adversaries, the human body and the organism of the disease—here, the tubercle bacillus. When the physician is called upon to intervene, he is required to take no less a part than that of "second" or backer to one of the combatants—the human body—and to fill this important post with success it is necessary that he should know something of the adversaries and their mode of fighting. He must do more, as a rule, than merely stand by and see fair play—he cannot, indeed, like Mephistopheles, step in and give the fatal thrust, since he has not the needful weapon—we possess at present no chemical means of destroying the tubercle bacillus *in situ*. He can, however, back up, encourage, and to some extent train the human body to greater and better chosen exertions, and also, perhaps, supply it with weapons for the fight. To do this successfully he must first of all inform himself by what means and with what weapons victory over the tubercle bacillus can be obtained.

What do we know about the fight?

We know first of all that soon after the tubercle bacillus has got a foothold in the body, the body becomes "sensitive" to this organism, so that when fresh bacilli are introduced or tuberculin given, a "reaction"—the tuberculin reaction—tends to occur. This and the subsequent rebound is the body's response to further infection or spread of disease, and the means, in all probability, whereby natural cure takes place. Bacillary products passing out into the tissues cause a series of these slight reactions and thereby the defensive mechanism is aroused, protective substances are formed and, at the same time, a useful hyperæmia is set up in the foci of disease. Where, on the other hand, the dose is excessive, as in cases of acute or advanced tuberculosis (compare also the overdosage of the early tuberculin era) reactions run riot and the body is overcome—fever, wasting and general illness mark the effect of the tuberculous poison or nervous and other tissues and the end is at hand.

The position is strikingly similar to that which may occur in human combat. A blow with the fist, if moderate, elicits a smart return—a knock-out blow, on the other hand, or a series of quickly placed smaller ones, will lay out our man. How are we going to train him to oppose the tubercle bacillus?

Firstly, phthisis has small beginnings—we must discover our enemy at an early stage, an early diagnosis is of the first importance. At this stage the bacillus is a poor fighter, our man can oppose him with a little coaching, and if we keep him up to the mark, will gain a ready victory.

If the enemy has got stronger, the disease more advanced, our man must be put into training against a smaller adversary at first. This is where tuberculin comes in, the initial dose being minute and rising gradually as the body is trained to oppose it. If, finally, we are only called in when the adversary has gained the upper hand or at any rate a temporary victory, we must keep off the enemy as much as we can while our man gets his wind—auto-inoculation must be reduced to a minimum by "typhoid" rest in bed. We must then "pad" our man against the enemy's blows—must produce tolerance to tuberculin, the poison of the bacillus, by accustoming our patient to larger and larger doses. The body is thus hardened, as it were, to withstand the punishment it is bound to expect. If the disease is advanced this can be but a temporary triumph, but in earlier stages it may improve the health sufficiently to allow arrest or cure to come about.

We have now got an idea of the lines which rational treatment of tuberculosis must take. In the first place we have the general health of the body to raise and to maintain throughout the struggle at its highest level. In the second place we must train it in the special warfare needed to overcome the tubercle bacillus.

Our subject finds, then, a ready division into general and specific treatment.

General Treatment or Health Building

Tuberculosis is conveniently classified under the headings Local and Autotoxic—in the first division come cases where the disease is strictly localised and the general health unaffected; in the second, disease of wider spread or affecting vascular and mobile organs like the lung, so that some amount of general illness results. It is obvious that under either condition the general nutrition, and nervous energy, must be considered as of the first importance, but the remarks which follow will necessarily apply in the main to autotoxic disease, such as phthisis, where special measures have to be undertaken to raise and maintain the general health.

Hygienic-Dietetic Treatment.—This is the equivalent of sanatorium treatment, but may be taken to cover all other measures of a similar kind. It is, of course, the first and most vital step in the treatment of tuberculosis, and the form in which it is best administered in an individual case often taxes to the utmost the knowledge and ingenuity of the physician.

Sanatorium treatment expresses its highest development, for here, in addition to the most efficient arrangements for climate, air, sun, soil and suitable diet, we have the constant supervision of a doctor highly trained in this branch of work, and the opportunity of specific treatment being carried out in competent hands. The sanatorium is the best start-off for all who can afford it, as it gives opportunity for special investigation in cases which need it, is almost essential in febrile cases and is the best place in which to start a course of tuberculin treatment. Failing the sanatorium, or after return from one, home treatment in a well-arranged shelter, of which a large number of convenient patterns are now on the market,[1] or between well-ventilated rooms and garden, may form the nucleus of a successful cure. Dryness, sunshine, and protection from prevailing winds are the main points to consider in the selection of an outdoor site, since these are the factors which most of all favour continued and comfortable open-air existence.

The main factors of Hygienic-Dietetic treatment may be considered under the headings of the Open-Air Régime, Climate, Diet, Rest and Exercise.

Open-Air Régime.—The most valuable effect of open-air treatment is the influence it exerts on the spirits and appetite, digestion, and all the bodily processes. It increases tissue change and supplies nervous energy, and there is good reason to believe that this is mainly brought about by skin stimulation and heat demand. For this reason cold, dry air and hot sun by day, such as are found to perfection in certain mountain climates, are the best. Failing these, and where these are contra-indicated, the driest place available must be sought, the clothing must be porous and not too heavy, and skin stimulation from sun and air and cold bathing or sponging encouraged. The patient must not be allowed to live in a tropical morass under his clothes, which may well happen if the conditions required are not understood. Under a reasonable skin stimulation and the corresponding increase of nervous energy all the functions of the body are performed at a higher level, nutrition increases, and the body is better able to respond to the demand for the formation of antibodies against the tubercle bacillus. It is, perhaps, on this account that the open-air régime exerts such favourable effects on the symptoms, especially fever, associated with auto-toxic disease.

Open-air treatment should be carried out in the spirit, but not made a fetish. It must be remembered that stimulation is only of value as long as it leads to efficient response; prolonged chilling only exerts a depressing effect. The patient must be reasonably covered, should immediately change wet clothes, is best protected from fog and mist, and derives no benefit from draughts.

Avoidance of mixed infections is a further most important factor in the value of open-air treatment, and a very temporary relaxation of discipline may wholly neutralise this good effect. Thus a visit to friends in stuffy rooms, an evening entertainment, the introduction of a household catarrh, may render nugatory the effects of open-air isolation.

Climate.—Climatic influences are of value, but they must not be overrated. Recovery does not wait on locality, however suitable, but rather on the troublesome routine which a suitable climate can forward but never supplant. The fame of health resorts for phthisis has been earned by their physicians and the opportunities these have for supervising the lives of their patients rather than by climatic excellence. Open-air treatment may be carried out and carried out efficiently almost anywhere, but when a choice of locality exists it must be wisely exercised. A well-chosen climate should, in the first place, encourage the open-air régime; in the second place, it should supplement it where needful. This it will do mainly by its heat-abstracting powers, and these depend on temperature, humidity and wind conditions. In all cases the patient's power of response is the test of suitability, and to determine this it is necessary to inquire into his personal experience of climates and the effects of winter, summer, cold and heat upon him. The young and vigorous respond well to a large heat demand, and for them the high Alps are well suited; the elderly do not well meet the call for increased tissue change, and warmer and less vigorous climates are better. In all cases a dry air is most suitable, for with dryness are associated abundance of sunshine and cool or cold nights—the changes of temperature are large but well borne and less likely to chill the surface than are smaller changes in a moist atmosphere.

First on the list come the *mountain resorts*, where the cold rarefied air and powerful sun exert a maximal influence on nervous energy and respiratory exchange, and lead to increased assimilation and renewal of bodily vigour. The Swiss Alps are most convenient of access, and such places as Davos, Arosa and St. Moritz are well suited to vigorous patients, especially for the winter months, and are staffed by able physicians. Every case should be put in charge of one of these, and it must be remembered that not all cases can stand the Alpine climate; advanced disease, especially when accompanied by extensive laryngeal tuberculosis, much emphysema and kidney disease are distinct

[1] See *Brit. Journ. of Tuberculosis*, 1912, VI. 124–128; also advertisements in subsequent numbers.

contra-indications. After the mountain resorts come certain *low level climates*, suitable on account of dryness of air, abundance of sunshine and shelter from excessive wind. The Riviera represents the dry coast climate, but has certain disadvantages. Excessive wind and dust are serious drawbacks, but still more so the less complete medical control patients will submit to in this neighbourhood, and the social temptations to which they are exposed. Dry hot air is obtained in the *desert climates*, of which Egypt and the neighbourhood of Algiers supply the most notable examples. Those places are especially suitable for cases with bronchitis or bronchiectasis, emphysema or kidney disease, where the high and cold climates disagree; they are, unfortunately, only available during a short period of the year. Places with moist climates, such as Madeira, seldom suit phthisis patients; where, however, a very irritable laryngeal complication is present a moist and dustless climate may be given a trial. There is no greater danger to a phthisis patient than to develop a "wanderlust" in search of health; the belief that recovery lurks in some distant clime and cannot be found nearer home is a fatal error and must be opposed.

The *English climate*, though marred by excessive moisture and cloud, yet gives quite successful results in the open-air treatment of most cases of tuberculosis. Attention must be given, as we have said, to individual peculiarities and also to the nature of the disease. Hardy patients will do well on the east side during the summer months and even in the winter. The south is more sunny, but also of moister atmosphere, especially towards the west—Bournemouth, Ventnor and Torquay being the best known on this coast. Many cases do better at inland resorts than the sea. Fortunately, sanatoriums now exist in most parts of the country, and changes can be made for time of the year and other reasons. But it must be remembered that the medical officer is always a more important factor than the climate surrounding his station.

Diet.—Fortunately the days of forced feeding for phthisis are no longer with us. It is recognised at length that obesity is only of disadvantage by throwing more work on the lungs—moreover, the increased fat, water and flabby cells are not the best fitted to respond to stimulation by the production of antibodies against the tubercle bacillus. What we need is quality, not quantity; we must strive for the optimum of nutrition, not the maximum, which is something very different. This is not to say that a patient may not be brought above his original body weight with advantage, but only that his "condition" is at least of equal importance with his weight.

The diet in tuberculosis presents few particular points—it should be that best suited to achieve ample nutrition in the particular patient. Individual and national tastes must be studied, but the patient not allowed to become too faddy. A mixed diet with a good proportion of proteids and fats is the best. All forms of meat and fish may be given according to the patient's digestive powers, and eggs are a convenient stand-by when full quantities of other proteids cannot be taken. Milk may be given, when it agrees well, with breakfast and tea, and at bed-time, and perhaps in the middle of the morning. Preparations such as Malt Glidine or Plasmon may also be used as additions to meals where required. Fats are well taken where the climate is cold, but may need reduction in hot weather; they may be given as cream, butter, fat bacon, or beef or bacon dripping, and should be well broken up by being eaten with bread or similar vehicle.

Cod-liver oil is also readily digested by many patients and forms a convenient vehicle for creosote if desired. Alcohol should be considered purely as a stomachic, but where a glass of beer or light wine improves appetite and digestion it may be given with distinct advantage. Attention must be paid to efficient mastication and the teeth put in the best possible condition, not only with a view to this, but also to eliminate the dangers of mixed infection arising from this source. Pyorrhœa must be looked for and kept in control where present.

The patient should be weighed every week at the same hour and in the same clothes, and a record kept on the temperature chart. It must be seen that the patient is not unduly depressed when the weight refuses to rise, since this may react on the progress of a case otherwise favourable.

Rest and Exercise.—The rôle of rest and exercise in the treatment of tuberculosis is but too little appreciated. In an autotoxic disease such as phthisis their regulation is of vital importance, and in practice it constitutes one of the most difficult problems ever presented to the physician. The effect of exercise on the temperature, and to a less extent on the pulse, forms the basis of control, and the following indications must generally be followed—

Rest in bed is required as long as there is fever; in case the temperature is uncontrolled by ordinary rest, "typhoid" rest, in which movements are as completely restrained as in typhoid fever, must be given a trial.

Exercise must be begun on the level; at first, where there has been fever, for only five or ten minutes daily and increased very gradually each week till four to six hours a day are reached. Daily exercise must be decided

by the temperature chart—a rectal temperature of 98·8 or over on waking, or of 99·8 or over at 6 p.m. are indications for bed, and slighter rises will necessitate slighter restrictions, such as a shorter walk or rest in a chair. An occasional day in "bed" supplies a useful "rest" chart by which to control the effects of exercise, remembering always that no temperature should be taken within an hour of active exertion. All patients, in spite of their ability to take exercise, should have complete rest for half an hour before meals and for a short time after.

Lawrason-Brown suggests the following printed rules as an aid to the co-operation of the patient in the matter of exercise and rest.

Rules for Exercise.

(Exercise means walking. Special permission must be obtained before indulging in other forms of exercise.)

None for one week after beginning treatment, then ask about it.

None if feverish.
,, ,, blood in the sputum.
,, ,, loss of weight.
,, ,, the pulse is rapid.
Never get out of breath.
,, get tired.
,, run.
,, lift heavy weights.
No mountain climbing.
Go SLOW.
Exercise regularly and systematically whether rain or shine.
Walk up hill at start so as to come down hill on return.
Remember always that you will have to return.
Rest one half-hour before meals.

Accessory Treatment. General Tonic Treatment.—The hygienic-dietetic treatment may be forwarded in many cases by the exhibition of certain drugs. These act in the main as tonics, often through the digestive organs. A simple alkali and bitter before meals is helpful to the appetite and digestion, even apart from any dyspeptic complaint; if the appetite flags, a minute dose of zinc sulphate ($\frac{1}{6} - \frac{1}{4}$ gr.) in a couple of drachms of some bitter infusion is often invaluable. Creosote and its derivatives have been much favoured in phthisis and are useful in all forms of tuberculosis. In moderate doses given after meals they appear to stimulate digestive functions, but injudiciously pushed or given when stomach catarrh is present they may cause marked gastric irritation. Beechwood Creosote (1 min. increased up to 5 min.) may be given in cod-liver oil, and this makes an excellent mixture during the colder parts of the year. Otherwise it may be taken in sherry or put up in capsules. Guaiacol (1–5 min.) is its most useful derivative, and thiocol (5–10 or 15 gr.) dispensed in orange syrup diluted with water makes a useful preparation for children. Cinnamic acid, as the salt hetol, has been extensively tried in tuberculosis with the purpose of causing a leucocytosis, but no definite clinical success has followed its use. Recently, extensive claims have been made for a mixture called dioradin (radio-active menthol iodine) in the treatment of tuberculosis; it appears to have been useful in cases of surgical tuberculosis, but its value in phthisis still lacks proof. Pneumosan (amyl-thio-trimethylamine) has been given in phthisis and other forms of tuberculosis with apparent increase of nervous energy and therewith improvement in the general nutrition and pulmonary symptoms. It is interesting that trimethylamine is present in cod-liver oil, especially, it is said, in the cruder brown preparations. Such drugs as arsenic, best given, perhaps, as sodium cacodylate (1 gr.) by intramuscular injection so as not to disturb digestion, iron, and the hypophosphites, may all find a place as tonics in the general treatment of tuberculous patients.

Symptomatic Treatment. — Treatment must be directed, where possible, to any symptoms which are distinctly interfering with the progress of the case. Thus fever, apart from its significance, may upset digestion and appetite, cough may cause auto-inoculation and so fever, pain may hamper calm respiration and prevent sleep. In treating such symptoms great care must be taken that we do not check natural response but only control it; also that we do not exchange bad for worse, as, for example, by destroying appetite and digestion in the injudicious treatment of cough. In a short article like the present, only a few indications can be given under these headings.

Fever generally points to activity of disease. It is important to distinguish between fever and high temperature, which is only the sign manual of this. Treatment of fever is all important and means elimination of toxæmia. Treatment of high temperature is truly symptomatic, and should only be undertaken when as a symptom its prominence is interfering with progress. All measures to prevent auto-inoculation by "typhoid" rest and to diminish cough and unnecessary talking must be first employed. Some patients with fever, especially children, will take their meals well in spite of it. The food should be nourishing but lighter than for apyretic patients, and the principal meals taken at times when the temperature is not high. Daily spongings with water, or alcohol and water, help, and the hands and arms may

be frequently so bathed. If required, a dose of pyramidon (2–3 gr.) or of cryogenin (3–5 gr.) may be taken a couple of hours before the principal rise, but temperature so controlled must be distinguished from genuine diminution of fever. In the right cases minute doses of tuberculin may bring down a temperature otherwise rebellious; in many cases a mixed infection is responsible for fever, and this must be sought for and in some cases a vaccine tried. The treatment of fever must never be simply symptomatic; the persistently febrile case is a case by itself both for prognosis and treatment.

Cough must be sharply divided into useful and useless. Where useless, and leading to auto-inoculation or disturbance of sleep, it will need some special attention. Often the patient does not realise how much he can control useless cough himself by determined repression, and he must be warned of this. Where, on the other hand, there is expectoration to bring up, efforts must be made to loosen it. Warm spray inhalations, or warm mineral waters or saline drinks will help, or a mixture containing ammonium chloride and some rectified spirit. Cough leading to vomiting may require gastric sedatives containing some opiate if necessary; the clearing of the tubes before meals with the help of warm saline expectorants may help to prevent this. For irritating cough, especially at night, a linctus containing heroin, codeine, (as Heroin $\frac{1}{24}$ gr., or Codeinæ $\frac{1}{8}$ gr., Acid Sulph. Dil. 2 min., Glycerine and Aq. Laurocerasi 10 min. of each, Syrup Tolutani up to 1 dr.), or morphine may be necessary, with careful avoidance of digestive upset. Dry inhalation from a respirator often quiets troublesome cough, such drugs as creosote with menthol, spirits of chloroform or ether being used (as Menthol 1 dr., Creosote 1 dr., Spirit Vini Rect. and Spirit Chloroform $\frac{1}{2}$ oz. of each)—acetone is invaluable in certain cases.

Pain must not be allowed to interfere with sleep and must be treated on general principles. *Night sweats* may be controlled by sponging at bed-time with dilute vinegar or brandy. An open-air régime, the use of porous clothing, and avoidance of too heavy covering do much to check them. Quinine may be tried in some cases, agaricin ($\frac{1}{12}-\frac{1}{8}$ gr.) or an atropine pill ($\frac{1}{200}-\frac{1}{100}$ gr.) is occasionally required for a time. *Indigestion* and *diarrhœa* will be treated on general principles and may necessitate a temporary alteration to a diet which is lighter and either more or less stimulating, according to the nature of the trouble.

Surgical Treatment.—Localised tuberculosis is often near the surface of the body and may call for surgical interference. This, be it noted, can never take the place of other treatment, both general and specific, but bears a similar relation to these as does symptomatic treatment. Surgical measures generally fall under one of three headings.

(a) *Excision of the Tuberculous Area.*—This is less often attempted than formerly; it is now well recognised that excisions can never remove the whole disease, and they should be reserved for cases where all but slight or quiescent disease can be taken away. This is occasionally the case with neck glands; but wide operations are being more and more replaced by conservative treatment.

(b) *Removal of Dead Material.*—This includes attention to bony sequestra, scraping of caseous glands, or their careful removal, often to be accomplished by mere aspiration of soft tuberculous material. Under this heading may come also the necessary efforts to secure adequate drainage in the case of large or deep tuberculous disease, especially where mixed infection is feared or already present.

(c) *Provision of Rest.*—In the case of tuberculosis of joints and mobile parts, rest must be provided to allow repair, and at times to limit auto-inoculation. This necessitates the employment of apparatus of various kinds—splints, jackets, suspension apparatus, weight and pulleys, and a host of other contrivances.

Specific Treatment

Under this heading come all measures directed against the cause of disease—the tubercle bacillus. Chemical poisons analogous to quinine in malaria, emetin in amœbic dysentery, and salvarsan in syphilis we have none, and we require to fall back on the laboratory of the body for the formation of protective or destructive substances. In the case of the tubercle bacillus the nature of these substances is still somewhat obscure. Looked at from the practical point of view specific treatment can be classified according to whether passive or active immunity is aimed at.

Passive Immunity, by the use of a specific serum, is successful in such diseases as diphtheria, where a powerful extracellular poison has to be neutralised, but is of doubtful utility in diseases like tuberculosis, where the poisons are retained in the substance of the bacilli. It is at present uncertain whether the anti-tuberculous serums, such as those of Marmorek, Maragliano or Ruppel exert some slight bactericidal or antitoxic effect, or whether any action they may have is similar to tuberculin, as Wright maintains. Clinical evidence in their favour is highly conflicting and doubtful. Spengler's I. K. claims to possess both passive and also active immunising properties.

Active Immunity, where the human body is required to manufacture its own antibodies, is the road to natural cure, and its judicious

regulation is the basis of rational treatment. Products of the tubercle bacillus, in other words tuberculin, form the stimulus; production of antibodies is the response. The stimulus must not be too great or exhaustion ensues; it must not fall too low or antibodies wane. Judicious treatment will aim at keeping the supply within bounds when excessive (reduction of auto-inoculation) or supplementing it when too low (tuberculin injections). The former of these aims may fail when the disease has progressed too far; it may be impossible to reduce auto-tuberculin to a convenient figure, and the attempt must then be made to neutralise its action. We possess no effective form of anti-tuberculin to inject from without. We must produce it from within, and, fortunately, by skilfully graduated dosage on a good system, such tolerance against the toxin can often be produced that tuberculin no longer exerts its action in doses where formerly it led to over-stimulation and illness.

We thus find that specific treatment concerns itself in the main with three indications, artificial stimulation of antibody formation by tuberculin, control of auto-inoculation, and the production of tolerance.

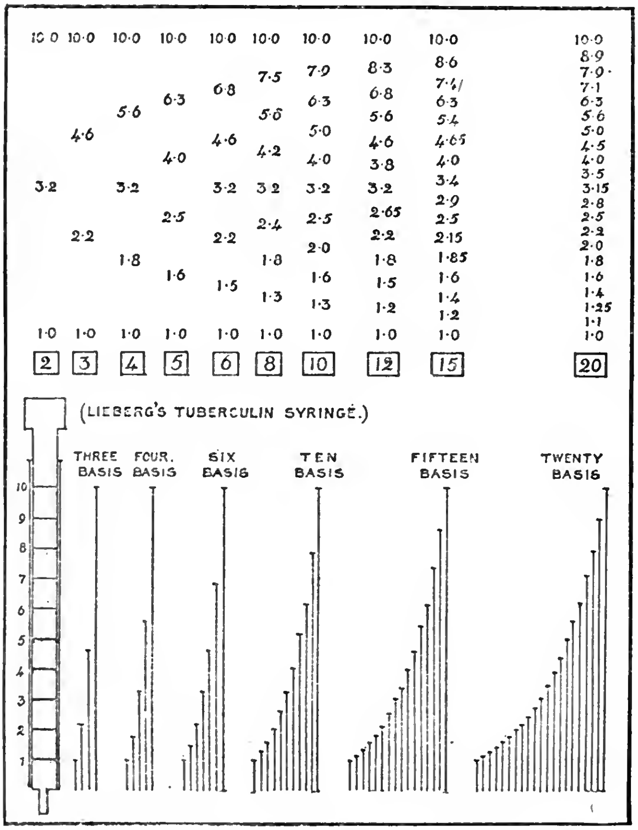
Artificial Stimulation of Antibodies by Tuberculin.—In localised tuberculosis, lupus, dactylitis and the like the supply of tuberculous products (auto-tuberculin) from the lesion may not be sufficient to stimulate production of antibodies and bring about a cure. In these circumstances and also with most forms of chronic and partly healed tubercle, it may be useful or necessary to introduce the stimulus from outside in the form of tuberculin. An efficient therapeutic dose of tuberculin gives rise to the following effects. A "reaction" occurs consisting of three parts: *local*—redness and swelling at the site of injection; *general*—fever, headache, malaise, etc.; and *focal*—congestion in the area of disease. This latter is of value in flooding poorly nourished areas of disease with blood. Accompanying the "reaction" is a temporary lowering of antibody content in the blood as exemplified by its opsonic power. After a day or two all these effects pass off and the patient feels well again—often unusually well. Antibodies increase in the blood, giving the "positive phase" of opsonic power, and the area of disease when visible begins to show signs of healing. This "rebound" after the "reaction" lasts some two or three weeks, and thereafter the effect of that dose of tuberculin is finished.

It is now time to give another dose, and this, if well chosen, is followed by the same effects, till by a series of these responses the area of disease in a favourable case is enabled to heal. This is the small-infrequent-dose method advocated by Wright and suitable for all cases of localised tuberculosis. The preparations T.R. or B.E. are especially suitable, the dose varies with the case and must be that which is just effective, and commonly 0·05–0·1 c.mm. (0·00005–0·0001 c.c.) of either preparation suffices for an adult, and a proportionate dose for a child according to its weight. It is well to begin below the average dose and increase it till a slight general disturbance or some hyperæmia at the focus of infection occurs, and to continue this dose till its activity wanes, when it again must be increased. An interval of two weeks between the doses is generally suitable, but it should be lengthened if a reaction occurs, and may be shortened where the dose is ineffectual. The large-frequent-dose method, and the principles governing it, will be described under the heading of *Production of Tolerance*.

Control of Auto-inoculation.—Though it is the production of tuberculin in tuberculous lesions which stimulates the production of antibodies, and so the cure of disease, the process very quickly tends to get out of control in an organ so vascular and mobile as the lung. Then occur the general symptoms associated with established phthisis—wasting, fever, dyspepsia, etc., due partly to the action of tubercle products—auto-tuberculin—and partly no doubt to poisons produced by the destruction of the body cells. These poisons pass from the foci of disease into the blood, and it is this process we speak of as auto-inoculation. Where the disease is considerable the supply is ceaseless, but with more moderate disease such auto-inoculation may only occur when the focus is submitted to increased vascularity. Such an increase especially follows increased function, and the control of auto-inoculation demands the reduction of function of the diseased organ to its lowest denomination. In the case of the lung all muscular movements, and even mental and emotional activity, increase its function, and control of auto-inoculation must be sought through complete bodily rest. The effectiveness of this control is best tested by temperature and pulse, and the amount of rest necessary to get rid of symptoms varies (see *Rest and Exercise*). In some cases a week's rest, or partial rest, in bed will suffice to abolish fever. In others "typhoid rest" over a long period with careful control of cough (see *Cough*) may be required. In cases where the disease has reached a certain stage of progress all measures may fail to eliminate the symptoms of toxæmia. In certain of these patients it may happen that the disease has remained to a very large extent one-sided; when this is the case, if toxæmia cannot be otherwise reduced the production of an artificial pneumothorax (collapse-therapy) may work wonders. It puts the diseased lung

at rest and thereby reduces absorption of auto-tuberculin, and at the same time favours conditions of repair. Where pleural adhesions render the production of a pneumothorax impossible, an extrapleural thoracoplasty, with removal of ribs, may be made to serve the same purpose in the same class of case carefully chosen.

It might be argued that all the effects of this control of auto-inoculation are likely to be undone as soon as the patient gets up again, and so they will, unless care is taken. The patient is now at the starting-point on the road to tolerance, just as we may bring a case of failing heart on the road to full compensation, or one of neurasthenia, at the end of a rest cure, on the way to full nervous stability. In each case the secret of final success lies in the "graduation" of the succeeding march—the upgrade must not be steeper than the maimed organ can cope with (see also *Rest and Exercise*).



Dosage in Geometric Progression (from *Tuberculin Treatment*, by Riviere and Morland)

The enclosed numeral denotes the "Basis" or number of doses to be given in each Dilution of Tuberculin before passing on to the next. A sensitive case is put on a high Basis—say [15], a tolerant case on a low—say [8]. In any series, every dose is the same multiple of the preceding one whereby all "cliffs" in dosage are entirely avoided.

Production of Tolerance.—Tolerance may be achieved either to tuberculin or to auto-tuberculin, and the former is probably the easier method to follow. With the patient still at rest we begin tuberculin in minute doses and rise by geometric progression, each dose being the same multiple of the previous one (see table), so that no sudden increase of dose may disturb the progressive compensation. By these means we are able to reach without much difficulty quantities of tuberculin a million or more times larger than that with which we started. We thus build up tolerance against both tuberculin and auto-tuberculin, in this way greatly ameliorating the symptoms of auto-inoculation. We are also able by well-arranged dosage to stimulate antibody formation and cause mild focal hyperæmia by each injection, and thus to use tuberculin as a remedy while saving the patient from the effects of its excess. This is the large-frequent-dose method suitable for all cases of autotoxic disease and especially phthisis.

It may be wondered how we are able thus to increase the dose of tuberculin, but the explanation is simple. Every dose of tuberculin is followed by a period of tolerance to reinjection. After a couple of weeks this tolerance has waned, but if the next injection follows in two or three days an increase of dose is needed to insure the same effect, and so larger and larger doses are given about twice a week without more immediate effect than equal small doses given at two or three weeks' interval. The value of this tolerance may be shown as well against auto-tuberculin as against tuberculin. A resting phthisical patient gets fever on rising, but if only one or two doses of tuberculin are given during rest and the patient gets up on the second day after a dose (*i. e.* in the phase of tolerance) there may be no return of fever. Since all cases of phthisis are subject to auto-inoculation from their lesions the intensive system of dosage described above is suitable to this disease.

Practical Points.—It is necessary to begin well below the reaction limit—a dose of 0·001 or 0·002 c.mm. (0·000001 c.c. or 0·000002 c.c.) of any tuberculin is convenient—and the dose may be doubled till some sign of reaction appears. This may be shown by slight local reaction, by a "flattening" of the temperature, or a slight general reaction, symptomatic or febrile. When this point is reached progression must be slow and regular on a basis of about eight to twelve doses in each dilution of tuberculin (see chart) according to the type of case.

The dilutions are made up each one-tenth strength of the next above. Thus dilution I consists of 1 c.c. of tuberculin made up to 10 c.c. with diluent (conveniently normal saline with 0·5 per cent. phenol); Dil. II is 1 c.c. of Dil. I (or one-tenth c.c. of tuberculin original solution) made up to 10 c.c. with diluent, and so on.

Thus—

1 c.c. of Dil. I	contains	100 c.mm.	(0·1 c.c.)	Tuberculin.
1 c.c. of Dil. II	,,	10 c.mm.	(0·01 c.c.)	,,
1 c.c. of Dil. III	,,	1 c.mm.	(0·001 c.c.)	,,
1 c.c. of Dil. IV	,,	0·1 c.mm.	(0·0001 c.c.)	,,
1 c.c. of Dil. V	,,	0·01 c.mm.	(0·00001 c.c.)	,,

And thus one-tenth c.c. of Dil. V contains 0·001 c.mm. (0·000001 c.c.) of tuberculin, the amount recommended for an average initial dose.

If only a local reaction occurs, the same dose is repeated till this wanes; if a general reaction occurs, and especially if focal symptoms, such as increased cough and expectoration are noted, rest in bed is required and the dose withheld until the temperature settles again. The next dose must be reduced $\frac{1}{2}-\frac{1}{10}$ according to the amount of reaction and the length of the interval for recovery. Where the local reaction is properly followed as a guide and no increase of dose made while it recurs, the course can often be completed without any general or focal reaction.

Recapitulation and Conclusion. *Localised Tuberculosis*, in its treatment demands attention to the following principles—

(a) *Hygienic-dietetic Treatment* or general health-building on the lines already laid down save that the difficulties arising from auto-inoculation are absent. On this account open-air and home treatment throughout is more often feasible, though climatic conditions and removal from towns is needed in certain cases.

(b) *Stimulation of the Defensive Mechanism* is especially needed in localised tuberculosis, since the supply of tubercle products from the area of disease is small. Tuberculin should be given on the small-infrequent-dose method.

(c) *Surgical Treatment.*—Removal of dead material—caseous material, hard or soft, bone, etc.—is occasionally required, establishment of free drainage where mixed infections are suspected or manifest, control of movement, and avoidance of deformity by apparatus. A second vaccine to combat mixed infection is occasionally required.

Autotoxic Tuberculosis, of which phthisis is the common example. Cases may be conveniently divided into three classes—

Class (a). *Resting Febrile* wherein auto-inoculation is excessive even at rest. Here the measures advised under "control" of auto-inoculation must be pursued with the hope of bringing the patient into class (b). These are cases for the sanatorium and the specialist, or are beyond the reach of all but palliative treatment. Not infrequently a mixed infection is responsible for their condition.

Class (b). *Resting Afebrile — Ambulant Febrile.* Where symptoms, such as fever, only appear on increased function. Here the indication is gradually to raise their tolerance, till they can be brought into class (c). For this skilled hygienic and specific treatment are necessary, and a course of sanatorium treatment is required at the outset, though the later stages in a favourable case can often be carried through successfully in the home.

Class (c). *Ambulant Afebrile.* — Where patients can go about without any symptoms attributable to auto-inoculation. These cases are especially suitable for home treatment—where means of ensuring hygienic-dietetic, and if possible specific treatment, are available. Often a considerable amount of quiet outdoor exercise and pursuits can be arranged with advantage, but always to the avoidance of fatigue and loss of weight, and also of violent movements which might cause injury to healing parts. C. R.

BACILLARY DYSENTERY

The treatment as regards rest and food is much the same as described under Amœbic Dysentery, except that brandy and opium are more likely to be needed. Bismuth and intestinal irrigation are also useful. Emetine has been found to be of no value in unmixed cases of bacillary dysentery, except perhaps for diagnosis.

Severe cases should be treated as early as possible by serum, or, if that is impossible, by salines, the rule being that the saline is given every hour until the motions become fæculent, and this is repeated daily for three days.

If the exact etiology is unknown, or if it is impossible to prepare an autogenous vaccine, a polyvalent serum, such as Shiga's, may be used.

In mild cases one injection of 10 c.c. into the skin about three inches below the clavicle may be enough to banish blood, mucus and tenesmus, so that the patient gets refreshing sleep. If not, repeat the dose in six to ten hours.

A bad case must have a similar dose twice daily for two or three consecutive days. The injection is to be subcutaneous, not intramuscular. The dose issued by the Lister and Pasteur Institutes is 20 c.c. Urticarial eruptions or pains in the joints, due to the serum, may require lactate or chloride of calcium, 15–30 gr.

For collapse, the subcutaneous injection of normal saline solution is useful.

Very severe cases, which are suspected to involve the whole of the large intestine, and gangrenous cases, may be treated by appendicostomy, which enables the whole large bowel to be washed out with a weak permanganate or boracic acid solution (1 in 160), or, if necessary, with collargol (1 in 500). F. M. S.

LEPROSY

No specific treatment has yet been found, but the recent discoveries showing that the bacillus of leprosy can be cultivated as a streptothrix, or as a bacillus, lead one to hope that some day a reliable vaccine may be produced.

Tuberculin was tried by some of us, at Koch's instigation, in 1890, and often since, but it cannot be recommended. Most drugs are useless unless they improve the general health of the patient. Chaulmoogra oil has apparently cured or arrested the disease, but it has often failed. If the stomach will tolerate it, give it in gradually increasing doses from 20–300 min. daily, either in capsules or in an emulsion with gum. Or it may be given in milk *per rectum*, and it may also be rubbed into the skin of the whole body twice daily. Patients take it best intra-muscularly, but this requires its administration from sterilised tubes, and painful lumps and skin eruptions occasionally occur in spite of attempted asepsis. I once published a temporarily successful result after five years' perseverance, but most patients will not continue any one treatment for years.

Nastin, a crystallisable neutral fat, prepared by Deycke from a streptothrix, and then combined with benzoyl chloride, has been on trial intra-muscularly since 1904; the results are, on the whole, disappointing.

X-rays have been found useful by Heiser in a few recent cases occurring in young, otherwise healthy subjects.

As regards drug treatment, Pasteur's ironical precept must be remembered: "Always hasten to take a remedy while it still has the power of curing!"

Surgical and ophthalmic treatment must be on general lines, as if the patient were not a leper. Tracheotomy is not often required, but it will prolong life when the larynx is invaded and dyspnœa has resulted.

Sulphur baths as an alleviation have been successfully used at Koussatz in Japan and in Egypt.

As regards general measures, the leper may be wise to leave the country in which he became infected, and he should lead the outdoor life of the converted consumptive, and wear specially warm clothing, because the involvement of his skin throws additional work upon his kidneys.

Prevention.—Leprosy in any country ought to be a notifiable complaint. Lepers with open sores, or any nasal discharge, should be isolated until the disease is arrested. The healthy children of lepers should be separated from their parents as soon as possible, and should then be kept under observation. Antiseptic precautions after handling lepers are necessary. There is no evidence that leprosy is due to the eating of any particular food such as fish.

F. M. S.

THE MYCOTIC INFECTIONS

In dealing with the therapeutics of mycotic infections it will be convenient to divide these diseases into three groups: (1) those in which the fungus invades the hair; (2) those in which it attacks the superficial layers of the glabrous skin or the nails; and (3) those in which there is invasion of the deeper parts of the skin, of the tissues beneath, or of the internal organs. Corresponding with these three groups there are three main forms of treatment: (1) when the hair is attacked, depilation (especially by X-rays); (2) the employment of local parasiticides when the infection is superficial; and (3) the administration of potassium iodide for the deeper infections. The reason for the employment of these different forms of treatment in the different circumstances will be presently explained.

1. **Mycotic infections of the hair** include the several varieties of *Tinea Tonsurans* and of *Tinea Barbæ*, and *Favus* of the scalp. Formerly in the treatment of these diseases, ineffectual attempts were made to kill the fungus by means of parasiticides. The multiplicity of the remedies employed is evidence of the ill success of such measures, for, owing to the depth to which the fungus extends in the hair, it is impossible that these applications should reach it. The more rational method is to remove the hair and with it the fungus. This cannot be done by epilation because the infected hair breaks away. Occasionally, by the older methods, one may succeed in attaining this object by the production of inflammation of the affected areas and consequent loosening and fall of the hair; but with the stronger remedies, such as glacial acetic acid, or croton oil, there is danger of permanent baldness of the parts inflamed; and the milder applications cannot be relied upon to produce an inflammation at will. Among the most efficacious are tincture of iodine (or Liq. Iodii fort used with care), Ung. Hydrarg. Nitratis, B.P., and an ointment of equal parts of common salt and vaseline. Repeated applications of either of these remedies will in a small proportion of cases, probably about 1 in 15, lead

to inflammation of the affected areas and consequent fall of the infected hair, with ultimate cure in the course of two or three months. But by far the most rapid and certain method of treating Ringworm of the scalp is by means of X-rays.

The X-ray Treatment of Ringworm of the scalp consists in applying to the affected areas of the scalp, or to the whole scalp, if the disease is at all extensive, measured doses of X-rays sufficient to cause depilation without danger to the skin. If there be only one to three patches of ringworm, each patch may be treated separately by exposure through a circular hole cut in a sheet of lead, and large enough to include a good margin of healthy hair; or a lead-glass cylindrical localiser may be used. When there are more than three patches it is generally advisable to depilate the whole scalp. This is done most conveniently by the "five-exposure" or "Kienboch-Adamson" method. By this method the forepart of the scalp, the crown, the occiput and the sides of the head each receive in turn a single Sabouraud pastille dose of X-rays. In order that there may be an even radiation of the whole scalp, it is necessary to aim the five doses at five equidistant points, and these points are to be carefully marked on the clipped or shaven scalp with a blue skin-pencil. The first point is in the middle line, an inch or two behind the anterior margin of the scalp. Five inches are measured backwards from this point to mark the second point on the crown, and again five inches for the point on the occiput. The two lateral points are marked just above each ear so that they are five inches from each of the three central points. The applications are best made with the patient lying down. The X-ray tube is enclosed in a lead-lined box-shield which has a circular aperture of three to four inches in diameter through which the rays pass towards the scalp. Around the aperture there are fixed three slender converging wooden pegs, the ends of which rest on the scalp and keep the shield and the contained tube at a fixed distance from the skin. The box must be so arranged that the blue-pencil mark on the scalp is exactly in the middle of the points of the three pegs. The anticathode of the X-ray tube should be 6½ inches from the skin, and the Sabouraud pastille exactly midway between the skin and the scalp. The five exposures are given at one "sitting," and the whole procedure occupies from an hour and a quarter to two hours. After the exposures no visible change occurs until the beginning of the third week. During the third week after the treatment the hair falls, both healthy and diseased. The fungus is not destroyed, but merely comes away with the hair upon which it feeds. For six weeks or longer the parts which were exposed to the rays remain absolutely bald, and then the new and healthy hair begins to grow. In the course of a few weeks it may be an inch or so long. A mild antiseptic ointment (Ung. Hydrarg. Amm. Chlor. dil.) or a lotion (Tinct. Iodii 1 oz., Spirit vini methyl 7 oz.) is applied to the whole scalp daily during the treatment in order to disinfect the skin itself. The child is free from infection so soon as the hair has completely fallen. The sole danger of the X-ray treatment is permanent loss of hair from an over-dose. But with modern methods the risk of such a serious occurrence, though perhaps not entirely eliminated even in skilled hands, is reduced to a minimum.

Favus of the Scalp is treated by X-rays in the same manner as ringworm.

Ringworm of the Beard is in many instances of animal origin and, as is characteristic of animal ringworms, spontaneously inflammatory. Depilation then occurs, in course of time, as a natural process, and the only treatment required is that of local antiseptics. One of the most useful is an ointment of oleate of mercury 5 per cent., with resorcin 15 gr. ad. 1 oz. The less inflammatory forms of beard ringworm are generally more quickly cured by X-ray treatment, though on account of the somewhat more difficult technique owing to the irregular shape of the chin, it is advisable first to try treatment by the ointment recommended.

2. **Mycotic Infections of the Glabrous Skin** include Tinea circinata, Tinea cruris, Eczematoid ringworm of the fingers and toes, Favus of animal origin and Tinea versicolor. These eruptions are for the most part readily cured by the application of local parasiticides, and there is no indication for X-ray treatment. *Tinea circinata* (or ringworm of the body) occurs in the form of scaly rings or patches in association with scalp ringworm, or it may be derived from the cat or the dog, in which case the rings are more inflammatory and often vesicular. Still more inflammatory and pustulating eruptions result from infections from horses or cattle. In all forms of Tinea circinata the local application of tincture of iodine is a favourite and an efficacious remedy, although it has the disadvantage of producing exfoliation or crusting, and may thus render it difficult to know when the disease is cured. For the pustulating ringworms there is no better treatment than a daily application of tincture of iodine. In the less inflammatory forms the ointment of nitrate of mercury is a well-tried and useful remedy, but the ointment containing benzoic acid, as recommended below for Tinea cruris, is probably better than any other application. *Tinea cruris* or ringworm of the groin (formerly called Eczema marginatum and known in India as Dhobie Itch) is usually regarded as an

obstinate complaint. The older treatments by application of iodine or by use of chrysarobin ointment (Goa powder of India) are objectionable on account of the local inflammation which they often produce in these parts where the skin is tender. They may now be discarded for a cleanly and rapidly efficacious ointment which we owe to Dr. Arthur Whitfield, as follows—

℞ Acid Salicylic gr. x-xv
Acidi Benzoici gr x-xv
Ol. Coca-Nucis ʒ vi
Vaselin ad. ℥ i

Eczematoid Ringworm of the Toes and Fingers.—Many so-called eczemas of these parts are really ringworm, and often associated with ringworm of the groin (Eczema marginatum). They are easily cured by benzoic acid ointment. *Pityriasis versicolor*, or Tinea versicolor, is a macular eruption of the chest and back due to a fungus (microsporon furfur) and seen often in phthisical persons, or those who sweat much and wear flannel. It may be cured by the frequent application of sulphurous acid, 1 dr. in 1 oz. of water.

Favus of the Glabrous Skin is occasionally met with in this country, at any rate in London, as a result of contagion from a mouse or a cat infected with favus. It occurs as red scaly, or vesicular, or crusted circles or rounded patches like those of ringworm of the body, but distinguished from the latter by the presence of one or more sulphur yellow favus cups or sculuta. The eruption is cured by removal of the sculutæ, and application of a local antiseptic, such as iodine or mercury.

Ringworm or Favus of the nail is best treated by covering the affected nails with a wad of wool soaked in tincture of iodine under a finger-stall. The cure takes several months. X-ray treatment or evulsion of the nail is usually unsuccessful.

3. **Mycotic infections of the deeper parts of the Skin, of the Tissues beneath and of the Internal Organs.**—These include actinomycosis and other forms of streptothrix infection, and the more recently discovered sporotrichosis and blastomycosis. The features of actinomycosis are described in all the text-books, and need not be recalled here. In *sporotrichosis* there occur gummatous lesions in the skin, sometimes in the muscles and bones, and very often in the viscera. They suggest those of syphilis or of tubercle, but yield cultures of a fungus called sporotrichum. The disease is fairly common in America, both North and South, and on the continent, especially in France, but a few cases only have as yet been discovered in this country. *Blastomycosis* is a disease due to a yeast fungus which manifests itself chiefly as local, fungating ulcers of the skin, but which may become a systemic infection. Most of the cases recorded have occurred in America. In both these affections, but particularly in sporotrichosis, the internal administration of potassium iodide in large doses (up to 60 gr. daily) may lead to a complete cure. Actinomycosis may also be cured by iodide of potassium, unless the disease is very extensive and accompanied by secondary coccic infection. In actinomycosis surgical treatment of total extirpation or of scraping, combined with local antiseptics, may also be employed. Surgical treatment in sporotrichosis or in blastomycosis is inadvisable. The action of iodide of potassium in sporotrichosis has been carefully studied by de Beurmann and Gongerot, who have shown that it produces its effect, not as a direct parasiticide, but as a stimulant of phagocytosis. These observers think it possible, however, that a bactericidal nascent iodine is also disengaged by the action of the living cells. Serum and vaccine treatments have been employed in these deep-seated mycotic infections, but hitherto the results obtained have been less successful than those from potassium iodide administration. H. G. A.

DISEASES DUE TO PROTOZOA

AMŒBIC DYSENTERY

Whether the case is acute or sub-acute, as usually seen out of Great Britain, or whether treatment is required for symptoms occurring in a case imported from abroad, *rest in bed* for at least a week is an essential which will do much to assist the cure.

A flannel belt or broad bandage should be worn by day and night, and for severe pain fomentations are necessary.

Rest is all-essential for the ulcerated intestines, so that in very severe cases the diet must be restricted to albumen water, rice water and whey. Brandy should not be given unless it is absolutely necessary.

In ordinary cases milk boiled, sterilised or peptonised, may be given diluted with rice water. Those who think they cannot drink milk may require the addition of sodium citrate, 5 gr. to each feed.

Every two hours a feed of about 4 ounces should be drunk very slowly, and it must be neither hot nor cold.

Soup and meat extracts are better avoided until the number of motions is lessened, when arrowroot, Benger's food, eggs and milk puddings may be cautiously added. Then soft food such as rusks, pounded fish, chicken and bananas, and, later, toast, chicken, pigeon, followed, in the fulness of time, by meat, vegetables and fruit.

A daily inspection of the fæces must determine the menu. Thirst may be relieved by allowing the patient to sip a simple acid lemonade or a solution of lactic acid (1 in 3000).

The preliminary general treatment is not unlike that of enteric fever, and the fæces must be disinfected or burnt and protected from flies, with equal care.

Drugs.—An initial aperient is necessary to get rid of the relics of previous improper diet, and it is surprising to find how much fæces are retained, even when twenty to thirty motions are being passed in the twenty-four hours. One dose of castor oil may be given, or drachm doses of sulphate of magnesium (with Tinct. Card. Co.), or from four to six doses of calomel, $\frac{1}{8}$ gr. with Sod. Bicarb., 3 grs. every hour.

Intra-cellular (not subcutaneous) injections of emetine hydrochloride should be given without delay; $\frac{1}{2}$ gr. once a day, increased, if necessary, to $\frac{1}{2}$ gr. twice a day. This valuable remedy, re-introduced in 1912 by Leonard Rogers, causes no depression, nausea nor vomiting, and is now being so much used that its market price has doubled since September 1912. The patient will probably experience slight tenderness at the site of injection on the succeeding day.

To try to obviate the cost of emetine, a rival preparation, amebetine, has been produced, which contains emetine unseparated from cephæline, another alkaloid of ipecacuanha; the dosage is similar to that of emetine.

Emetine can also be administered by the mouth if the drug is sufficiently coated by keratin.

Emetine treatment should be continued for at least two weeks, and may have to be re-commenced if amœbic cysts are found later in the fæces.

Tenesmus can be checked by small enemata of saline solution or by suppositories of cocaine, opium or belladonna. Hæmorrhage from the bowels must be treated by an ice bag on the abdomen, opium, calcium lactate or digitalis by the mouth, or enemata of iced water.

If the fever accompanying the dysentery is thought to be malarial, quinine must be given.

As soon as convenient, it is well to put the patient on bismuth, preferably the salicylate, 15 to 30 gr. every four hours, and to continue this for at least two months.

The treatment should be prolonged after all symptoms have disappeared to prevent possible relapses and development of liver abscess.

Obstinate chronic cases, which do not yield to two different courses of emetine, prolonged bismuth and careful rest and dieting, may be benefited by Plombières treatment, as carried out in France or at Harrogate or in London.

Former Treatments.—1. If no emetine can be procured, recourse must be had to the best Brazilian ipecacuanha, which was introduced into England as a cure for dysentery late in the seventeenth century. The following method was employed at the hospital connected with the London School of Tropical Medicine in the pre-emetine days. The patient must be starved for four hours, a mustard plaster is applied to the epigastrium, and the patient is made to lie flat in bed without any pillows. Fifteen min. of laudanum in water are then given, and after a quarter of an hour 30 grs. of ipecacuanha powder. To prevent vomiting, the patient is kept rigidly at rest, the nurse, sitting by his side, is ordered to wipe away saliva to avoid his making any movement, and no food is given for at least three hours after the dose. On the next night the same treatment is carried out, except that the ipecacuanha is reduced to 25 gr. and the laudanum to 10 min. On the third night the ipecacuanha consists only of 20 gr., preceded by 5 min. of laudanum. On the fourth night laudanum is discontinued altogether, and the ipecacuanha is further reduced to 15 gr. On the fifth night, 10 gr., and on the sixth night, 5 gr. of the drug are given. The treatment is then continued with a nightly dose of 5 gr. for another week or ten days. In spite of the vomiting and the annoyance of having to lie absolutely still, this treatment has proved to be most useful, and the amœbæ are found to disappear from the stools after the second or third dose. In order to lessen the risk of vomiting, the ipecacuanha may be administered in "membroids," or in stearin-coated pills.

2. Saline treatment every day by drachm doses of sulphate of magnesium with or without sulphate of soda, succeeds when ipecacuanha fails; it has been thoroughly well tried since 1877, when Bartholow of Ohio introduced it.

3. When acute symptoms are arrested, intestinal irrigation is often useful once or twice a day, the drugs used being, of course, those which will kill the amœbæ *in vitro*, e. g. quinine 1 in 5000, increased to 1 in 500, nitrate of silver, 1 in 1000, or sulphate of copper, 1 in 1000.

Whichever drug is employed the routine method is the same. A long tube and funnel, or a reservoir containing 3 pints, are indispensable. The rectal tube must be at least 3 feet in length and soft enough to avoid injuring the bowel; after being well greased, with boric vaseline, it should be introduced, if possible, its whole length. The fluid is not injected, but allowed to run in slowly during some minutes. The patient should assume the knee-elbow position, or else the buttocks must be raised on pillows, and the foot of the bed elevated on blocks. If the anus be very sore

from many acrid discharges, it may be painted with cocaine before the operation, or a suppository of one grain of cocaine may be inserted half an hour before the irrigation. Until the patient becomes accustomed to the treatment the tube should be passed by the medical attendant himself. All adult patients can hold one pint, rapidly increased to 2 pints, and some can gradually accustom themselves to take 4 pints or more. The enema need not be retained more than five minutes, and need never be given more than twice a day. As a rule, an enema of this kind every morning is enough, and in the evening a simple cleansing enema, such as 2 pints of saline solution, or water in which 1 ounce of linseed has been allowed to soak for some hours. This soothing enema may be retained by the patient as long as he likes. All enemas must be given warm.

It is obvious that any drug used is absorbed to some extent, for I have seen temporary poisoning after large enemata of boracic acid, starch and water, and similar cases have been recorded.

Sceptics who do not believe that the irrigation gets beyond the rectum may need to be reminded that bismuth, introduced by enema, has been seen by X-rays to have reached the cæcum.

Prevention.—Water and milk must be boiled, salads and uncooked vegetables eschewed, and butter and ice considered suspect, while food must be guarded from flies, dust, excreta and doubtfully clean hands. Children and young people should be specially protected by suitable clothing, regulated diet and avoidance of fatigue.

F. M. S.

SLEEPING SICKNESS

We have no specific drug for sleeping sickness, such as quinine in malaria, mercury in syphilis and salvarsan in yaws, yet there are several remedies in use which greatly benefit or even cure the condition. In the early days arsenic in the form of liquor arsenicalis was used, and it is of interest to note that at least two of the cases so treated recovered. Later the arsanilates, atoxyl and soamin, were introduced and better results were obtained with them, but unfortunately when used in large doses over prolonged periods of time, optic neuritis is apt to develop. Arsenophenylglycin, an organic arsenical compound discovered by Ehrlich, various benzidine dyes, antimonial salts, mercury salts in combination with atoxyl, and more recently salvarsan, have also been tried.

The antimony treatment has apparently succeeded in several cases and has been fairly extensively tried by Sir Patrick Manson at the London School of Tropical Medicine.

Dr. Newham, the director of that institution, has very kindly supplied me with the details of the method, these being as follows: The salt used is the *Antimonium Tartaratum*—potassio-tartrate of antimony or tartar emetic—the dose employed being from $\frac{1}{2}$–$1\frac{1}{2}$ gr. This is carefully weighed out and added to 4 oz. of normal saline in a glass flask, the neck of which is then plugged with cotton-wool. After this the flask is boiled for ten minutes over a bunsen burner, this completing the solution of the drug and also sterilising the mixture. A second flask containing 10 oz. of normal saline is also prepared and sterilised at the same time. The apparatus for the injection consists of a yard of soft rubber tubing ($\frac{3}{16}$ in. bore). A small glass funnel is inserted into one end of this while a fine silver canula fitted with a stop-cock is attached to the other. Sterilise carefully. Next select a superficial vein in the leg or arm. Sterilise the skin over this by painting with tincture of iodine and inject a little novocain near the point to be opened. Dissect out the vein for half an inch and apply two ligatures at either end of this. Tie the distal one, leaving the ends long for the purpose of holding and steadying the vein. An opening is then made above this and the canula of the injection apparatus, which is filled with normal saline heated to a temperature of 102° F., is inserted, the proximal ligature being tightened around it to keep it in position.

An ounce or two of normal saline is then allowed to run slowly into the vein, and if the flow is satisfactory and no leakage is taking place the tartar emetic solution, also heated to 102° F., is poured into the funnel and gradually allowed to enter. The rate of flow is controlled by means of the stop-cock on the canula, or by raising or depressing the funnel, and should not exceed 1 oz. of fluid per minute. When most of the tartar emetic has run in and only a small amount remains in the funnel, some 3 oz. more of the normal saline solution are added so as to wash out completely all the antimony solution into the vein. When only a little of this is left, turn off the stop-cock and slowly withdraw the canula from the vein. Before this is completed an assistant ties the proximal ligature as soon as the point of the canula has passed the spot where it (the ligature) encircles the vein, thus completely occluding the vessel and preventing the ingress of air. The ends of the ligatures are then cut short, the wound is closed by a suture, and suitable dressings are applied.

Throughout the operation great care must be taken that the funnel is never allowed to become empty of fluid, otherwise air will enter the vein.

Also the tartar emetic solution must on no account be allowed to escape into the tissues, otherwise an extremely painful necrosis is sure to follow. Provided the solution is run in slowly and the dose has not been too large, no special symptoms are produced by the injection, but in some instances a paroxysmal cough appears and a feeling of oppression in the chest is complained of. Alarming symptoms, twenty minutes or so after the injection, have been recorded, namely, severe rigor, high temperature, vomiting and collapse.

When atoxyl is given it must be administered intravenously or intramuscularly. Todd, of the Liverpool School of Tropical Medicine, recommends the following procedure: Make a 20 per cent. solution of atoxyl in normal saline, warm to blood heat before using, and inject the following doses: 0·6 c.c. every day for four to six days, then raise to 0·8 c.c. for another four to six days, then again raise the amount to 1 c.c. per day. Continue to give this dose until signs of intoxication begin to appear. When this happens, reduce it, as in the ordinary administration of arsenic, until the limit of the patient's toleration is reached, and keep the dose at that point.

As already stated, the danger of giving excessive doses of atoxyl lies in the production of optic atrophy, leading to total blindness. Smaller doses (3 gr. or so) alternating with antimony and other drugs are still given by some, and undoubtedly prove useful.

Broden, Rodhain and Corin have recently given salvarsan an extended trial in the treatment of sleeping sickness cases in the Congo. Doses of 0·4 and 0·6 gm. were given intravenously. These observers conclude that the drug has a rapid and energetic action on the trypanosome, and that it also has a beneficial action on the patient. Further trials should, therefore, be given to it.

Whichever line of drug treatment is adopted, it must be clearly understood that the fight for mastery over the trypanosome will be a long one. Such being the case, it is all important to build up the patient's strength in every way by good food and good hygiene, so as to prepare him for the struggle. Chills must be very carefully avoided, intestinal parasites if present must be expelled, malaria and syphilis, if present, suitably treated, and every effort made to avoid over-exertion or anything that may cause debility. G. C. L.

KALA-AZAR

The treatment of this common and important Eastern disease cannot be said to be satisfactory. The mortality due to it has been variously estimated from 75 per cent., after long courses of quinine (Price), to 98 per cent. in untreated cases or in cases treated by other methods.

Rogers in India has recommended, and still recommends, large doses of quinine, 60 gr. or even 90 gr. a day being given for considerable periods of time. These doses, though in some instances distressing to the patients, often change the high remittent types of fever seen in this disease into harmless low intermittent ones and otherwise ameliorate the symptoms. A certain percentage are said to recover. Castellani and Chalmers also believe that the best method of treatment is by the administration of quinine in massive doses, supplemented by a course of quinine cacodylate injections or atoxyl injections. One of their patients apparently recovered on a treatment of quinine sulphate (30 gr.) and euquinine (30 gr.) daily by the mouth, together with a daily intramuscular injection of quinine hydrochloride (15 gr.) alternating with one of quinine cacodylate (4 gr.). Manson, on the other hand, believes that these massive doses of quinine are not only useless but harmful, and certainly in some of the cases I myself have seen at the London School of Tropical Medicine no amelioration of symptoms followed such a line of treatment.

Atoxyl has appeared to do some good in certain cases, Manson having treated four patients with it. In two no improvement followed, but in the others a cure seemed to result. Further trials by other observers have not confirmed the value of the drug, however.

Of other drugs tried one may mention arsenic, methylene blue, cinnamate of soda, senega, trypan red and antimony. Intravenous injections of the latter have been very efficacious in some cases of human trypanosomiasis, and an extended trial should be given to it in kala-azar. Salvarsan is also certain to be tried, but as the disease is in no way related to spirochætal maladies the efficacy of this drug will probably be nil. Rogers treated three cases with staphylococcus vaccine, and they recovered, but as they had also been treated with large doses of quinine it is uncertain to which of the remedies, if either, one must attribute the success. Vaccines prepared from the Leishman Donovan parasites themselves are still *sub judice*. X-rays have also been tried, but have failed. Occasionally, remarkable spontaneous recoveries from an apparently hopeless state take place, and, as Rogers says, much caution is required in making deductions regarding any line of treatment—such recoveries, however, encourage the hope of the ultimate finding of a curative drug.

The rest of the treatment must be purely symptomatic. Any parasitic worms present

should be got rid of. The patients should have good food and be kept in the best of hygienic conditions.

Hæmorrhages are often troublesome. For these calcium chloride may be tried. If from the nose, Tinct. Hamamelis (Hazeline) or other styptics will be found useful, or the nares even may have to be plugged.

Diarrhœa is to be controlled by opium and astringents. Ascites, if extensive, will require tapping.

Prophylaxis.—There are good grounds for believing now that the *Leishmania donovani*, the causative parasite of the disease, is transmitted from man to man by the bites of insects. Patton in India incriminates the bug. This insect should be destroyed, therefore, wherever possible, and no one should sleep in houses where kala-azar patients reside or have resided unless certain that they are scrupulously clean and free from bugs. The destruction of old bug-infested coolie lines in Assam and the building of new ones is said to have greatly diminished the disease in these parts.

G. C. L.

MALARIA

Malaria, though known to Hippocrates, was never scientifically studied until after 1639, when cinchona bark was imported into Europe by the Countess of Chincon, wife of a Viceroy of Peru, who had been cured of malaria by it. By means of this drug Charles II was cured of a tertian fever in 1679, but it was not until 1820 that quinine was shown to be the active principle of the bark.

Unless the patient is comatose or otherwise dangerously ill, it is better to postpone the administration of quinine until the diagnosis is firmly established and until it is clear which form of malaria has to be dealt with, and at what hour the paroxysms are likely to occur. It must be borne in mind that if the patient has recently taken quinine it is often impossible to find the parasite in the peripheral blood.

Quinine is the specific drug which is certain to cure malaria, if only the prescriber understands how to use it, but there are three essential points in addition. Bodily rest is important, and quinine is more effective when the patient is confined to bed. Bed should, therefore, be insisted on in cases of sub-tertian infection.

The diet should consist during the fever, and for twenty-four hours after its cessation, of nourishing liquids, but after that the patient may have any ordinary digestible food.

The bowels should be freely opened by small repeated doses of calomel ($\frac{1}{6}$ gr. every hour), as early as convenient; this improves the patient's condition and favours the action of the quinine. For the sake of others, the patient must be protected from mosquitoes.

Choice of Quinine Salt.—There are more than twenty varieties, of which only six need be mentioned here.

1. Sulphate is the oldest and best known. It should never be used for malaria, because it is difficult to digest, requiring 800 parts of cold water to dissolve it. This necessitates the use of a dilute acid with it, which often causes indigestion and constipation, for which the quinine gets the blame.

2. Bisulphate is soluble in eleven parts of water, and is exactly the same price as the sulphate. This is an ideal salt for governments and hospitals.

3. Bihydrochloride is soluble in two parts of water and is the salt invariably used for intra-cellular injections. The objection to this salt is that its price is nearly double that of the bisulphate. It is excellent for private patients.

4. The hydrochloride is preferred by some (soluble 1 in 40 of water) because it is a little cheaper than the bihydrochloride, which they also think is too soluble.

5. Euquinine is better taken by children and some delicate people, but it does not prevent cinchonism. It is seven times more expensive than the bisulphate.

6. The tannate has the advantage of being almost tasteless, and, in a chocolate basis, is well suited for children.

Time of Administration.—When a malarial paroxysm has begun, quinine will not check it and will only make the patient more uncomfortable; it is, therefore, better to wait until the sweating stage, or the fever-free period. By this method the quinine comes into contact with the youngest forms of the parasite, on which it acts most vigorously. Our aim is to give it four hours before the rigor, that is, before the sporulation of the parasite is due. If the hour of the expected rigor is unknown I give quinine in three separate doses, at 6, 8 and 10 a.m. to anticipate the rise of temperature, which is often in the afternoon. The quinine treatment must be continued for at least two months in the mildest cases, and for periods varying from three to six months in severe cases.

Methods of Administration.—1. If there is no vomiting or diarrhœa, it is better to give quinine by the mouth in solution, capsule, cachet or uncoated tablet, for ancient pills and coated tablets sometimes pass through the alimentary canal unabsorbed.

2. Treatment per rectum is unsatisfactory, whether by enema or suppository, because absorption is slow and irritation is caused.

Moreover, 50 per cent. more than by the mouth must be given.

3. The intra-cellular method (not subcutaneous) acts more quickly and does not irritate the stomach. Painful hard lumps are sometimes caused at the site, but careful asepsis prevents the risk of abscesses. The syringe and needle, after being boiled, should be sterilised by carbolic solution, 1 in 20, to counteract any tetanus spores which might be present in the tropics. (See article on *Tetanus*.)

4. Intravenous injections are used when the patient is already comatose and there is great need of hurry, as in pernicious infection with sub-tertian parasites. Fifteen gr. of quinine bihydrochloride should be dissolved in 2 pints of saline solution, and injected slowly with the point of the needle directed towards the heart. The pulse should be carefully noted during the injection.

5. Suckling children can be treated by giving quinine to the mother, or quinine powder can be put directly into a child's mouth, and the mother can give the breast or bottle immediately to prevent unnecessary crying, spluttering and vomiting.

Dosage.—There is only one exception to the rules under this heading. If large, ordinary doses of quinine are given to a resident in a blackwater district, or even to one who has recently returned to Europe from a blackwater district, and if the individual has not recently been taking quinine regularly, an attack of blackwater fever may be produced even in the British Isles. Lest there should be any mistake upon this point, and lest it should colour the erroneous view that quinine is dangerous because it produces hæmoglobinuric fever, I wish to state that it is rather the want of regularity in taking the quinine than the excessive dose of the drug which accounts for the occurrence of this awkward, and sometimes dangerous, complication.

In such cases, instead of giving the ordinary dose at once, it is better, if the patient is not dangerously ill, to re-educate the internal organs to a large dose of quinine. This can be accomplished by beginning with such small doses as 1 gr. three times a day, and gradually increasing during a week to treble that dose, until eventually the ordinary dose can be given without fear. During this period of re-education the urine should be carefully watched and measured, and the patient should be in bed.

Let us now take the case of a malarious individual in whom there is no obvious risk of producing blackwater fever. For an adult less than 5 gr. or more than 30 gr. in the twenty-four hours are useless. It must never be forgotten that quinine is a mild poison, and restraint must be laid upon the evil doer who, to compensate himself for previous neglect of the drug, offers to take unnecessarily large doses, such as 60 gr. This is waste of good quinine and brings legitimate quinine treatment and quinine prophylaxis into disrepute. Ten gr. every two hours up to 30 gr. in each twenty-four hours, continued for two successive days, will, provided it is given after the paroxysm, prevent temporarily the recurrence of tertian and quartan fevers. Then give 5 gr. three times a day for a week, and follow that with 5 gr. daily for three months. With the sub-tertian variety give 5 gr. every four hours on the first day and then continue it every six hours for a week.

If used intracellularly, the periodicity will be broken by injecting 8 gr. every day for three days.

Salvarsan, 0·6 gm. injected, has been successfully tried by others in cases which are said to be refractory to quinine. I have never met a case of malaria which did not yield to quinine properly administered, but I have seen one English lady who suffered from hæmorrhage from the mouth and gums and into the skin after three tonic doses of quinine, each 2 gr. People with this rare idiosyncrasy should, of course, never visit a malarious country. Except salvarsan, which is still on its trial, there is no efficient substitute for quinine in malaria.

Cinchonism can be mitigated by adding Acid Hydrobrom. Dil. 20 min. to each quinine dose, but not by substituting Quin. Hydrobrom.

Symptomatic treatment consists chiefly in giving warm drinks and extra blankets during the cold stage, sponging in the hot stage, and strychnia or camphor when the heart is weak.

Ordinary antipyretics are harmful, but an occasional dose is permissible to secure sleep. Some Europeans still believe that they can cure themselves of malaria by inducing copious sweating. Cachexia requires a good climate, iron, arsenic, Warburg's tincture and fatty food.

Peripheral neuritis, enteritis and other complications will generally yield to prolonged treatment with quinine. When malaria is complicated with pregnancy it is to be remembered that malaria will probably empty the uterus, even if quinine be withheld, and also that large doses of quinine will not act upon a normal gravid uterus.

Prevention.—This is not the place to speak of public measures, but a brief note may be given of personal and domestic prophylaxis.

The "tenderfoot" should be warned of three axioms: 1. To regard his mosquito net as his most valuable possession, unless his house is mosquito-screened with wire gauze. The net must be in perfect repair and arranged outside the poles so that insects outside cannot bite

the sleeper through the net. While travelling the net must not be forgotten.

2. There is a special danger of being bitten between sundown and bedtime, because the insects are then lively and hungry and man is tired and sleepy. If there is no mosquito-screened balcony a wise individual will specially protect his feet and legs, and will not despise anointing himself with citronella or lavender oil.

3. Quinine must never be regarded as a substitute for mosquito screening, but 5 gr. should be taken regularly every day by an adult and half that quantity by a child. If this is not enough a double dose should be taken on Sundays.

Punkahs and electric fans are disliked by mosquitoes. No standing water nor breeding pools must be allowed near the house, and all old tins, bottles and puddles must be banished.

F. M. S.

BLACKWATER FEVER

Bed, warmth, fomentations to the loins, trained nursing and an initial purge of calomel and jalap are essential. If vomiting prevents a powder being retained, a soap and water enema should be given; also ice to suck and small doses of champagne or brandy.

The great thing is to keep the kidneys acting, so the urine must be measured, and the drinks should consist of barley water, albumin water, whey, tea, weak chicken broth and plenty of aerated water. Later, milk, peptonised food and meat juices may be allowed.

If the vomiting continues or the kidneys fail to act, give normal saline solution *per rectum* or subcutaneously or even intravenously. A hypodermic injection of morphia will sometimes relieve the vomiting and the backache. Anuria may require cupping to the loins.

A dose containing Sod. Bicarb. 10 gr., and Liq. Hyd. Perchlor. 30 min. is usually given every two hours for one day and then every three hours until the urine improves in colour.

It is better, if possible, to avoid quinine during the attack and then give it by the educative process described under malaria dosage. The patient should continue to take quinine for at least six months and should convalesce as soon as possible in a non-malarial country.

Prevention.—Rules as for malaria. The patient must be taught before his return to the tropics not to neglect mild attacks of malaria. If he has a second attack of blackwater fever he should not be permitted to return to a malarial country, because it is evident that either he has neglected proper precautions, or he has some special liability to hæmoglobinuria.

F. M. S.

RELAPSING FEVER

Salvarsan is now the specific treatment; 0·2–0·3 gm. injected intravenously causes the temperature to fall to subnormal in seven to fourteen hours, with a disappearance of spirochætes from the blood. As a rule there is no relapse, but if one occurs a second injection may be given.

Deaths have been recorded after a dose of 0·5 gm., so that some authors prefer to use neosalvarsan, which is less toxic. Rectal and intramuscular injections are less satisfactory than intravenous. There is every reason for supposing that this new treatment is equally serviceable for the various types of relapsing fevers in Europe, Asia, Africa and America.

Patients should be given as much fresh air as possible, and an unlimited quantity of water to drink. Salicylates relieve pain in the limbs and head, constipation requires sulphate of magnesia, and during convalescence diarrhœa must be guarded against by not prematurely permitting solid food. Quinine is useless excepting as a much-needed tonic after the fever.

Prevention consists in avoiding native huts and old camping-grounds which harbour the lice, ticks and perhaps bugs, which convey the disease to man. A mosquito net at night protects to some extent from these insects, but care must be exercised in inspecting any bedding which may have been used by natives, or which has been under their care.

Tick Fever. See *Relapsing Fevers.*

F. M. S.

YAWS

Within the last two years (1911–1912) it has been clearly shown that salvarsan or neosalvarsan are specifics in yaws much in the same way as they are in syphilis. Alston in Trinidad, Strong in the Philippines, Castellani and Perry in Ceylon, Cockin in Grenada, Hughes in St. Lucia, West Indies, and Sabella in Tripoli, have all reported marvellous results from its use. Some of these have used the drug intramuscularly, others intravenously, and though the latter is probably the best method of administration, yet the former seems to be quite efficient. Various doses have been tried by the different observers. Sabella, mentioned above, gave an adult male 0·7 gm. of neo-salvarsan intravenously, a woman and a thirteen-year old boy 0·4 gms. The effect of the drug was immediate, the man being cured in fifteen days, the other two patients in shorter periods. Other cases received 0·4–0·5 gm. of neosalvarsan also by the intravenous method. One dose generally effects a complete cure.

Perry in Ceylon treated fifty-four cases, the

doses used for adults varying from 0·3–0·6 gm. of salvarsan, either by the intramuscular or intravenous methods. The results are described as "little short of miraculous," granulomata disappear very rapidly, bone pains quickly vanish and deep tertiary ulcers heal in three weeks or so.

Hughes in St. Lucia advocates 0·6–0·8 gm. of salvarsan to adults and also is enthusiastic about the results obtained. Under old methods of treatment the average duration of stay in hospital was three months; by the new method it is twenty-seven days or less, a saving of over two months. An average dose of salvarsan for an adult may, then, be put down as 0·6 gm. One dose is generally sufficient to bring about a complete cure. If small doses are given originally, relapses may occur, but these can easily be cured by a second injection. In addition to the drug treatment, the patient's health should be improved as much as possible by good food, tonics, fresh air, sea bathing where possible, and mild aperients. Chills are specially to be avoided. Mercury and potassium iodide are now things of the past and need only be mentioned. Ulcerations and sores should be kept clean and dusted with some antiseptic dusting powder. It is astonishing how quickly these heal up after salvarsan. During convalescence an iron arsenic and quinine tonic will be found useful. G. C. L.

SYPHILIS

The present-day treatment of syphilis can be divided into two heads: (1) Local; (2) General.

Local Treatment.—A chancre should be excised when possible; if in a position which contra-indicates excision the sore should be cauterised, or frequently bathed with Lotio Nigra and Unguentum Hydrarg. well rubbed in until every trace of the induration has disappeared. Ung. Hydrarg. should also be rubbed in the skin over any enlarged lymph glands. Condylomata should be frequently bathed with antiseptic lotions, then kept dry with a powder which contains calomel.

℞ Hydrarg. Subchlor. gr. x
Magnes. Carb. gr. xx
Zinci Oxidi
Xeroformi āā gr. x
Pulv. Amyli ad. ℥i
M. f. Pulv.

Rubbing in a mercurial ointment will hasten the disappearance of any syphilitic skin lesion.

The local application of Iodipin with or without Tinct. Bellad., according to the severity of pain, will assist in bringing about the resolution of a periostitis. For joint affections Scott's dressing is the best application. For chronic ulcers cleanliness is the chief point to attend to, and when the ulcer is clean, either the use of a mercurial ointment or the judicious employment of Scarlet Red will assist in the general treatment. It must not be forgotten that any scabs should invariably be removed because their proteolytic action on the tissues underneath may increase the ulceration, although the primary cause has been got rid of. The local application of salvarsan to chronic ulcers on the leg or to the tongue, in chronic glossitis, often affords great relief. A 0·1 gm. ampoule dissolved in ½ oz. water or glycerine should be applied two or three times a day for a few days.

General Treatment.—Three drugs only need be considered, mercury, iodine and arsenic.

Mercury.—The best method of prescribing mercury is in the form of inunctions, but these are useless, except in congenital syphilis, unless carried out by a trained rubber. Mercurial inunctions are messy, and cause the patient some inconvenience, owing to the time they take up. More convenient are mercurial injections. The insoluble preparations are more efficacious than the soluble. The strongest compound is the subchloride, but unfortunately its use is so frequently accompanied by pain and occasional abscess formation that some preparation of metallic mercury is better. The best painless Grey oil is the following (Captain Adam's formula)—

℞ Hydrarg. 20 parts
Anhydrous Lanoline 30 parts
Chlorbutol 2 parts
āā by weight
Liq. Paraffin to 100 by measure
5 ♏ = 1 gr. Hg.
Sig. Inject. 5–10 ♏ weekly.

Injections can be made either into the buttocks or scapular muscles.

The insoluble preparations, of which asurol is the best, are now seldom called for owing to the rapid action of salvarsan, but if this is contra-indicated and the symptoms are such that the patient should be got under the influence of mercury as soon as possible, daily injections of 1 c.c. 5 per cent. Asurol sol. (= ·02 gm. Hg.) or Enesol (salicylarsenate of mercury) should be given. Injections every other day of 0·025–0·10 gm. of Antiluetin, an antimony salt, can be prescribed as an alternative if required.

When a patient cannot get regular medical attendance, mercury should be taken internally in some form; if this method causes depression or sets up gastro-enteritis or diarrhœa, a suppository of 1 gr. of mercury salicylate in Oleum Theobromi ½ gr. inserted every night just before going to bed will often meet the difficulty.

For use in the tropics suppositories will require to be made up with an extra amount of wax.

Iodine.—No preparation has yet been discovered which is so potent as potassium iodide, but unfortunately there are so many people who cannot take it. A mixture of the sodium and ammonium salts is better tolerated, but an idiosyncrasy may be shown to every inorganic salt, in which case an organic salt should be tried, for preference iodoglidine. The non-staining iodex ointment is an excellent local application.

Arsenic.—Fowler's and Donovan's solutions are useful alternatives, but the powerful specific is salvarsan, and its derivative neosalvarsan. Neosalvarsan is possibly not quite so strong as salvarsan, but it is easier to use, and causes fewer toxic symptoms. Moreover, intravenous injections can be given in the consulting room, and the patient allowed to go home immediately afterwards. Both can be used for intramuscular injections, but the necessary bulk is so great, that much pain and induration may follow. Another great disadvantage of the intramuscular route, which necessitates several injections, is that, as there is no guide as to the amount of the drug that has been absorbed, there is no indication when it is safe to repeat the injection. "Ioha" is the best preparation of salvarsan for intramuscular use, and for neosalvarsan the proportion of 1 gm. dissolved in 22 c.c. of pure distilled water.

Intravenous Injections.—Before submitting a patient to this treatment he should be thoroughly examined and prepared as for an anæsthetic, in the matter of aperients and diet.

Salvarsan—

Dose for man, 0·4–0·6 gm.
Dose for woman, 0·3–0·45 gm.
Dose for child, 0·001 gm. per pound weight.

The glass tube containing the powder should be thoroughly examined before the contents are dissolved, to see that there has been no air inlet.

The contents of one tube of salvarsan should be slowly dissolved in three or four ounces of warm physiological 0·9 per cent. saline which has been prepared with freshly distilled water, in a ten-ounce graduated glass measure.

When the powder has completely dissolved after sufficient stirring with a glass rod, 10 c.c. of double decinormal [1] sodium hydrate solution should be added, with the result that a precipitate forms; this precipitate is dissolved by a further addition of sodium hydrate, usually about 10 c.c.—this may be either more or less, according to the actual acidity of the powder. The 10 c.c. should be added slowly, and the mixture stirred thoroughly. By using a weak solution of sodium hydrate we avoid the risk of making the solution too alkaline, and the exact quantity required is more easily estimated. When the solution is quite cleared by adding the sodium hydrate, the measure should be filled with saline up to ten ounces, and once or twice filtered through muslin or several layers of plain gauze, so as absolutely to exclude even the smallest solid particle from getting into the vein, where it might cause either a pulmonary embolism or hemiplegia. Ten ounces must be considered the maximum dose.

Two points must be observed concerning the saline. In the first place, the sodium chloride must be chemically pure (Merck); secondly, the solution must not be less than 0·8 per cent. or more than 1·0 per cent. A hypotonic solution is more dangerous than a hypertonic, because the former causes hæmolysis—setting free the hæmoglobin from the red-blood corpuscles. Should this happen the patient may collapse after the injection, and there may be hæmoglobinuria. Needless to say, every vessel used should be sterile and the sodium hydrate solution should be boiled before use.

To warm the solution, a hot jacket should be placed around the measure and the whole placed in a water-bath; the jacket of gauze prevents the glass vessel from cracking. When injected the fluid should be at exactly body temperature, as the reaction following is considerably greater when it is too hot.

Another vessel filled with saline is placed by the side of the one containing the "606". The patient comes to the side of the bed and hangs his arm over, then a tourniquet [2] is placed on the arm, and the limb made to rest on a table in as comfortable a position as possible. The bend of the elbow is then sterilised by first rubbing with acetone and then with ordinary tincture of iodine.

When a vein cannot be seen it can often be felt, and should be marked out with a blue pencil to indicate its course. If this cannot be done, a vein should be exposed by an incision, either under a local or a general anæsthetic. There is no danger in a general anæsthetic, for the subsequent reaction is not in any way influenced. Hitting the bend of the elbow, or warming the arm with hot towels, will often make a vein prominent. An intravenous injection may be the simplest or one of the most difficult operations possible. A common trouble is due to the vein slipping

[1] Double decinormal NaOH or $^{n}/_{5}$ NaOH = 0·8 per cent., or 8 gm. to the litre of distilled water; normal sodium hydrate being a 4 per cent. solution.

[2] The simplest and best tourniquet is some rubber tubing, which should be wound tightly around the arm and the two ends fixed with pressure forceps, which can be removed without disturbing the limb.

about when the needle tries to pierce it; extending the arm as much as possible, or pulling the skin taut to fix the vein, may prevent this.

The solution can either be injected or infused, injection being far preferable, as—

1. The needle is not so easily dislodged. If this should occur while the solution is flowing in, by infusion some must escape into the tissues before the flow can be stopped; with the syringe merely a few drops need escape, as the tap can be turned off at once.

2. The operator has more control over the proceedings.

3. There is less danger of air or a solid particle gaining access to the vein. Air is easily seen in the syringe and remains at the top, never coming over the centre of the outlet unless the piston is pushed right home. A solid particle is also seen; it falls to the bottom of the syringe and is not disturbed, provided that the solution is injected slowly and steadily and the piston not rammed home.

4. The operation is pleasanter from the patient's point of view, because it is so much quicker.

5. The risks which are alleged to follow injection, and not infusion, do not exist in actual practice.

6. The operation can be performed without an assistant, and there is practically no apparatus to carry about.

A good syringe is one invented by Schreiber, and made by the firm B. B. Cassell, Frankfurt a. M. The cannula is bayonet-shaped, bent, and fixed to a three-way metal stop-cock, so that the fluid can be sucked up from the vessel and injected directly into the vein. The needle has also a plate at its base upon which a finger can rest to keep it steady. The one disadvantage of this syringe is that the whole apparatus is rigid; therefore the slightest movement of the syringe may be sufficient to dislodge the needle.

To overcome this difficulty, Allen & Hanburys have constructed for me a needle, which is 1¼ in. in length, behind which is a slightly concave metal plate which rests on the arm and is fixed by a piece of tape which runs under a metal bridge and is tied under the arm. This needle is fixed by means of a bayonet-catch to the three-way stop-cock; but the connection between the needle and the bayonet-catch is made by a piece of thick rubber tubing, so that every movement of the stop-cock or syringe behind is broken by this flexible connection and does not affect the needle.

The all-glass syringe, which should hold 20 c.c., fits on to the stop-cock by means of a piece of stout rubber tubing, instead of being inserted into a metal tube, which may not fit every syringe.

The syringe is first filled with saline solution and all air expressed both through the tubing and the needle, then the needle is inserted into the vein, and fixed with the stop-cock open. If the vein has been pierced, which can at once be told by the touch, or by blood flowing back into the syringe, the tourniquet should be removed and some saline injected. If the cannula is not completely in the vein, the saline will produce infiltration; this being the case, the needle should be withdrawn and another vein chosen, as it is most important to prevent any of the '606' solution getting under the skin, as considerable pain is caused thereby. If much escapes there will be painful induration and œdema of the arm, which takes weeks to disappear. When the solution has all been injected, some saline should finally be used to avoid leakage of a drop or two of "606", which is done by transferring the tubing from the "606" vessel to the one containing saline. If, during the injection, the needle slips and some of the solution escapes—the patient complaining at the same moment of a burning sensation—one should immediately take the needle out, apply a tourniquet to the arm, and allow the vein to bleed, which will often prevent infiltration forming. If the injection is skilfully done, the patient has no pain. In no circumstances must the preparation be injected in a concentrated form, and great care should be taken not to inject it too quickly.

Neosalvarsan.—1·5 gm. neosalvarsan equals 1·0 gm. salvarsan. Neosalvarsan oxidises quickly, and the oxidised product is toxic, therefore the solution must be prepared immediately before use and not shaken or stirred more than is absolutely necessary. The water in which the powder is to be dissolved must be warm enough to inject, and not above 30° C., and should be warmed before the powder is dissolved. Apyrogenetic water must be employed, without the addition of NaCl or NaOH 35 c.c. to 0·1 gm. of powder. The average dose can vary between 0·45 and 0·9 gm. Both salvarsan and neosalvarsan can be injected intravenously at weekly intervals.

The best procedure of treating syphilis in its various stages is, in the primary and secondary stages to give as many weekly injections of salvarsan or neosalvarsan as are necessary to procure a negative Wassermann's reaction in the blood withdrawn the day of the last injection. By this means the patient gets one injection after his blood becomes negative. In the primary stage between three and five injections will be required and in the secondary between five and nine. In the primary stage an examination of the blood should be made before treatment is begun. In both cases four courses of eight weekly intramuscular

injections of mercury should also be given and iodides prescribed for three weeks after each course, then six months, and a year later the Wassermann's reaction should be tested and a provocative injection of salvarsan given before a cure can be pronounced.

In the latent stage, diagnosed by giving a provocative injection of salvarsan, the treatment should be the same as above described. It is no use giving a provocative injection unless at least six months have elapsed since the patient last had an injection.

In the tertiary stage, when a cure in the strict sense of the word is practically unattainable, it is best to prescribe two injections of salvarsan to get rid of the symptoms, with a subsequent course or two of mercury and iodides.

In syphilis of the nervous system salvarsan should only be urged in cases of cerebro-spinal meningitis. In tabes it may occasionally do good when mercury has failed, but an aggravation of symptoms may occur. In General Paralysis of the Insane salvarsan should never be prescribed.

In congenital syphilis salvarsan should only be given when mercury fails to cure the symptoms, and mercurial treatment should be continued for at least three years. The treatment should be intermittent and alternating, *i. e.* one course should consist of inunctions, another of Hydr. c̄ Cret. given internally, and another of wearing clothing next to the skin which has been impregnated with mercury.

Pregnant syphilitic women should be given four or five injections of salvarsan as soon as conception is known to have occurred, and mercury continued throughout pregnancy.

Last but not least, oral hygiene should never be omitted when a patient is taking mercury; cleaning the teeth with pebeco and washing out the mouth and gargling with potassium chlorate or a 1 in 20 solution of perhydrol after each and every meal should be considered imperative. A lotion containing some formalin, tincture of myrrh and rhatany for hardening the gums is often useful. J. E. R. McD.

DISEASE OF UNKNOWN ETIOLOGY

RAT-BITE DISEASE

This peculiar disease, which is very common in Japan, has recently been reported in England, America and Italy. In many of its features it resembles spirochætal or protozoal diseases and is probably due to some similar germ. Ogata in Japan, indeed, believes he has discovered a sporozoon parasite, but his researches have not been confirmed. At varying periods after the bite of rats, during which time the original wound has healed and probably been forgotten, the site of the bite inflames and breaks down and constitutional symptoms develop. These briefly consist of febrile attacks, often separated by definite apyrexial intervals, peculiar erythematous skin eruptions, enlargement of glands, œdemas, pains in the muscles and joints and sometimes albuminuria. Recurrences are common, and the disease runs a prolonged course, in some instances for a year or more. Up to the present time treatment has mostly been symptomatic, though various drugs have been tried. Amongst these are quinine, antipyrin, phenacetin, aspirin, sodium salicylate, sodium sulphocarbolate, pilocarpine, arsenic and atoxyl.

Hata recently (*Münchener med. Wochenschrift*, No. 16, 1912) describes eight cases of the disease in Japan which were treated by salvarsan. In most of these marked improvement followed the injection of the drug, the temperature falling, the inflammation subsiding, the skin eruptions disappearing and the lymph glands resolving. In two cases relapses appeared, but in those the dose had been a small one, 0·3 and 0·4 gm. If further observations confirm the value of salvarsan in this disease then the probability of a spirochæte being the cause will be greatly strengthened. G. C. L.

DISEASES DUE TO TREMATODES

Distomiasis

Fasciola hepatica—Fasciolopsis buski—Paragonimus westermani—Clonorchis sinensis

Fasciola hepatica.—This, the common liver fluke, is met with occasionally in man—the diagnosis is made by finding the characteristic ova in the stools. The parasites live in the liver, inhabiting the bile ducts, and cannot, as far as we know, be influenced by drugs. Treatment must, therefore, be palliative.

Fasciolopsis buski (Synonym, *Distomum crassum*).—This is the largest trematode infecting man; it occurs in China and the East. It inhabits the upper part of the small intestine and in some instances has given rise to recurring attacks of diarrhœa with typhoid-like symptoms. Thymol or eucalyptus given as in ankylostomiasis often bring about their expulsion.

Paragonimus westermani (Synonym, *Distoma pulmonale*).—Found in Formosa, the Philippines, and in parts of Japan and China. The parasite inhabits the lungs and other tissues of man. Its presence in the lungs gives rise to a disease known by the name of endemic hæmoptysis. This is differentiated from tuberculosis by the finding of the characteristic ova in the sputum. As regards treatment, no means of expelling the parasite from the lungs have been discovered. Drugs are useless. If much fœtor and expecto-

ration exist antiseptic inhalations will be found of use. The life-history of the parasite is unknown, so prophylaxis must only be tentative. A pure water supply should be ensured and all forms of uncooked food should be avoided.

Clonorchis sinensis (Synonym, *Distoma sinense*).—Another Eastern fluke or trematode parasite inhabiting the bile ducts and gall bladder. In severe infections the liver tissue degenerates and clinically attacks of jaundice and diarrhœa are met with. There is no specific treatment, though salol has been said to be beneficial and might be tried. Removal from the endemic area to prevent re-infection is indicated. As regards prophylaxis, drinking impure water and eating raw uncooked foods should be avoided. G. C. L.

Bilharziasis. See *Schistosomiasis*.

Katayama Disease. See *Schistosomiasis*.

SCHISTOSOMIASIS

Schistosoma hæmatobium—S. japonicum.

The two diseases which require mention are (1) Bilharziasis, due to the deposit in the tissues of countless eggs laid by the Schistosoma hæmatobium worm, mostly in the bladder, urethra, ureter and rectum; this complaint is well known in Lower Egypt, the Transvaal and other parts of Africa, and (2) Katayama disease, occurring in Japan and China and affecting the abdominal organs of the alimentary canal by a deposit of the eggs of Schistosoma japonicum. The treatment of (2) is only symptomatic at present and may be included in that of Bilharziasis.

No method has yet been discovered of killing the worms in the human body. Liquid extract of male fern 15 min. three times a day, in appropriate mucilage, is the only drug of known value, not as a cure, but to mitigate symptoms. In many cases it controls or abolishes hæmaturia, allays bladder irritation and reduces temporarily the number of eggs passed in the urine or fæces. It should not be continued for more than a fortnight at a time, lest it produce poisonous effects, such as giddiness, pain in the head and epigastrium, singing in the ears and vomiting. There is no reason why a course of this drug should not be given several times in a year, alternated with courses of salol, 12 gr. three times a day, or urotropin or urodonal as urinary disinfectants. Methylene blue 3 gr. in a wafer once a week acts as a bladder analgesic, but cannot be considered a serious treatment; if given, the patient should be warned of the discoloration of the urine.

Care must be taken not to discourage the patient by letting him suppose the malady to be incurable, for it is not a pleasant thought to a refined person to be told he is infected with worms which cannot be evacuated. I have seen some neurotic patients much depressed mentally by an unnecessarily gloomy prognosis. One-fourth of the British soldiers who contracted Bilharziasis during the war in South Africa are still, after ten years, passing ova in their excreta, but there is no reason why they should not lead an ordinary life with moderate exercise.

Hæmostatic injections into the bladder for hæmaturia are dangerous, but early cystitis is relieved by washing out the bladder with boracic acid or boro-glyceride.

When the case is complicated by a vesical calculus, the lithotrite should be used, even if there is severe cystitis. Lithotomy does not give perfect results, but in boys under four years of age, when the stone is large, perineal or suprapubic lithotomy is permissible. When the patient is in the last stage of the disease, with the bladder filled with growth, in constant pain with a continual dribbling of foul urine, the only way of attempting assistance is to drain the bladder through the perineum by Cock's puncture or by suprapubic puncture, and keep a double tube in for eight to ten days. For acute retention of urine, when the bladder is full of blood clots and the catheter draws off no urine, perineal section is again called for; then gently break up the clot with the finger, wash out the bladder and the bleeding will cease; if it does not cease, wash out the bladder again with creolin solution, hot or iced. Urethral fistulæ are cured by a free excision of the fistula and the surrounding tissues.

Perineal fistulæ must be scraped with a sharp spoon and the wound left open to allow granulation; plug the wound and tie any vessels, but it is not necessary to tie in a catheter; perhaps several operations will be required for this common complication, but perseverance will effect a cure.

Bilharzial growths of the vulva must be excised. When the rectum is affected, relief may be afforded by suppositories of belladonna or by small enemata of starch and opium, or by sulphate of copper (1 in 1000). Rectal tenesmus is caused by growths near the sphincters, so help can be given by cutting away the mucous membrane and stretching the sphincters, then swabbing the rectum with a solution of chloride of zinc (1 in 10) and washing out with saline solution. Prolapse of the rectum can be treated by the lineal cautery, and if that fails to relieve, excision may be attempted, of course preserving the sphincters.

Prevention.—The eggs in excreta should be rendered harmless by patients passing them not into water but into dry latrines, where the embryos cannot develop into miracidia. Hatching can also be prevented by formalin (1 in

160). Bathing and paddling in doubtful streams or ponds must be avoided. The relative severity of Bilharziasis in Egypt as compared with other parts of Africa is probably due to repeated re-infection. F. M. S.

DISEASES DUE TO CESTODES

Tæniasis

Dibothriocephalus latus—Tænia solium—Tænia saginata

Dibothriocephalus latus, the broad tapeworm, is seldom met with in England. Its presence in the intestine is usually associated with a severe anæmia which may closely resemble pernicious anæmia. Treatment should be directed firstly to the expulsion of the parasite, secondly to dealing with the anæmia by arsenic, iron and nourishing food.

Tænia solium. Tænia saginata.—Many drugs have been advocated for the expulsion of these common tapeworms. Filix mas (male fern) still holds the first place. As the success or non-success of the treatment largely depends on how the drug is administered, the steps are given in detail.

Place the patient on liquid diet for two days. On the afternoon of the second day calomel or some other aperient is given and some soup or milk in the evening. Next morning, say at 7.50 a.m., a cup of black coffee is taken and then between 8 and 8.30 a.m. 2 or 3 capsules, each containing 30 minims of freshly prepared Extractum Filicis Liquidum are administered (*i. e.* when 2 capsules—60 min.—are given, one at 8, the other at 8.30. When 3 capsules—90 min.—are given, one at 8, one at 8.15, one at 8.30). To prevent vomiting one drachm of brandy, to which 15 min. of chloroform have been added, is sometimes given with the first dose. Two hours later a saline aperient (Epsom salts, Carlsbad salts, or sodium sulphate) is swallowed, and then after that the whole or portions of the tapeworm or worms are passed.

Precautions.—Never give castor oil as the purgative, because the poisonous filicic acid is soluble in oily substances and is then readily absorbed. Never give more than 120 min. (4 capsules of 30 min. each), this being the maximum dose that can be given with safety. The maximum dose given here is 90 min., but on the Continent the larger dose of 120 min. is often used. The poisonous symptoms that may appear are: (1) in mild cases, jaundice; (2) in moderately severe cases, violent vomiting, abdominal pain, a feeling of feebleness, syncope and somnolence; (3) in very severe cases, cerebro-spinal paralysis and death in a few hours.

Failures to expel the parasites may be due (1) to a bad quality of the drug, (2) to too copious secretions of mucus in the intestines, (3) to special powers of resistance sometimes possessed by the parasites.

The only way to be certain that one has succeeded is to find the head of the parasite, and it is important, therefore, to examine carefully all that comes away through a strainer. The head is small, about the size of a pin's head, and may easily be missed. After treatment the stools should be watched carefully. If segments appear again in about three months' time then either the head has not come away, or there have been more than one tapeworm present in the intestine. Whenever these are seen a second course of filix mas should be at once given.

Other drugs that have been employed in the treatment of tapeworm are pomegranate, sulphate of pelletierine, kousso, pumpkin seeds, turpentine, thymol and eucalyptus oil. The two latter are the usual drugs given in the treatment of ankylostomiasis, but as they frequently cause the expulsion of distomes and tapeworms when used in that disease they might be given a trial in tæniasis, especially if filix mas should prove unsuccessful.

Prophylaxis of Tæniasis.—This is largely met by the proper inspection of meat in slaughter houses, measly pork (pig's flesh infected by the *Cysticercus cellulosæ*) and beef infected with the *Cysticercus bovis* being condemned.

Prolonged cooking will destroy the cysticercus stage of the tapeworm, so all meat, especially if any suspicion attaches to it, should be well roasted or boiled. The ingestion of underdone meat is dangerous if cysts of tapeworms are present in it.

Tænia echinococcus.—Cysticercosis (Somatic tæniasis). Echinococcus disease is now usually divided up into two forms, (*a*) the form due to the *Echinococcus granulosus* (Syn. *Tænia Echinococcus*), and (*b*) the form due to the *Echinococcus multilocularis*, the latter causing the multilocular or alveolar form of hydatid disease.

The *Tænia echinococcus*, a very small tapeworm, inhabits the intestines of dogs, wolves and jackals; its eggs when taken up by man or other animals form the cysticercus stage—the well-known hydatid cysts. These cysts may occur in any of the organs of the body, and if of large size may often require surgical treatment. When in the abdominal cavity one must always remember the danger of allowing the escape of any of the fluid contents of the cyst. If such occur, a general dissemination of daughter cysts, brood capsules, or scolices leading to a multiple infection may result. Suppurating cysts such as are often met with in the liver must, of course, be dealt with surgically.

Prophylactic Treatment.—Dogs harbouring the adult *tænia* are dangerous. The intimate contact that exists between man and pet dogs at the present day, in the light of our recent knowledge, is decidedly risky. Undoubted instances of infection in this way have been recorded. Dogs, then, should be kept in their proper places and should not be handled more than necessary. Stray dogs should be destroyed and kennels should be periodically disinfected by boiling water or chemical disinfectants.

Echinococcus multilocularis.—This form of hydatid disease, though occurring in man, is chiefly found in cattle, especially in Germany, Switzerland, the Austrian Alps, Russia and Eastern Siberia. It is absent from Iceland and Australia, where the other form is so common. Dogs, as far as is known, do not participate in its spread. Until the life-history of the parasite is worked out prophylaxis must remain unsatisfactory.

Cysticercus Cellulosæ.—This, the cystic stage of the *Tænia solium,* is sometimes met with in man. It seems fairly common in India, where several cases have recently been reported. Once acquired no treatment is of much avail. Prophylactically, we must aim at the reduction of the adult worms generally, so preventing chances of infection with their ova. G. C. L.

DISEASES DUE TO NEMATODES

Filariasis

Filaria bancrofti—Filaria loa—Filaria volvulus—Filaria medinensis

Filaria bancrofti.—The adult forms of this parasite inhabit the lymphatic glands or lymphatic vessels in any part of the body, the embryos, sometimes called microfilariæ, the blood stream. No drugs, as far as is known, have any effect on either of these forms. Pathological phenomena, depending on the situation taken up by the adult parasites are not infrequent. The most common of these are filarial abscess, filarial lymphangitis, chyluria and elephantiasis. Filarial abscesses must be opened and drained; they quickly heal up after the removal of the pus. Filarial lymphangitis is often associated with high fever, rigors, vomiting and delirium. The affected part, most commonly one of the lower limbs, swells up, becomes red and painful, while the glands in the femoral region swell and are very tender. The patient should be put to bed, placed on a milk diet, the affected limb elevated and fomented with some mild antiseptic and a brisk purge given. In three or four days the temperature falls and all the symptoms subside. After repeated attacks, a certain degree of permanent swelling may remain. In chyluria and lymphuria the patient must rest in bed and avoid fatty foods. Retention of urine owing to clots in the bladder may be troublesome. Women who have suffered should not be allowed to become pregnant, as this greatly aggravates the condition.

Elephantiasis must be dealt with surgically. Short of amputation many operations have been devised to facilitate the escape of the stagnating lymph.

Filaria loa.—The adult worms live in the connective tissues, and may, in their wanderings, come into the eye. When seen here they may be seized with forceps and removed. Calabar swellings, fugitive swellings about the size of a pigeon's egg or larger need no special treatment, they go away by themselves in three to four days. There is no drug treatment.

Filaria volvulus.—This variety of filaria forms small subcutaneous tumours under the skin. They are of a permanent nature and may erode the skin and so form open ulcers. They should be excised.

Filaria medinensis.—The female guinea worm when it wishes to deposit its embryos comes to the surface and presses on the skin with its head. A blister forms over this which bursts and the embryos are discharged through the uterine opening which lies beside the mouth. There are two ways of treating the guinea worm. (1) By pouring water on the skin of the limb near the aperture daily and so getting the worm gradually to empty her uterus. After this is accomplished the end of the body is tied to a match and little by little is gradually wound out. The patient should rest in bed during this procedure and the limb should be wrapped up in some mild antiseptic. If suppuration occurs along the track of the worm it may be troublesome and will require incisions. (2) By injecting perchloride of mercury into the worm—this kills the parasite and also sterilises it. It then resembles a piece of catgut and is absorbed. Theoretically this is the better of the two ways, but practically the results are often uncertain, so much so that the first or older method is still generally adopted.

Trichinelliasis (Synonyms *Trichiniasis, trichinosis*).—The *Trichinella spiralis* (old name *Trichina spiralis*) is a common parasite of rats. The adult forms live in the intestinal canal and here give birth to embryos which are supposed to be deposited by the female into the lymphatic vessels. From here they are carried to the muscles, where they come to rest and become encysted. Pigs become infected by eating rats and ultimately show the encysted embryos in their muscles (trichinosed pork). Man eats this and so in turn acquires the infection. The dangerous time is when the embryos are passing from the intestines to the muscles.

Once in the muscles treatment does not affect them, but every effort should be made to dislodge the adults from the bowel. Calomel, salophen, salol and thymol have been recommended. The first of these is given in 10 gr. doses cautiously increasing to 20 gr. if the patient will stand it; the second in 30 gr. doses thrice daily; the third in 10 gr. doses and the fourth as described under ankylostomiasis. During the attack the general condition of the patient must also be attended to.

Prophylaxis.—Proper meat inspection and the thorough cooking of all meat, especially pork.

Trichocephaliasis.—The *Trichuris trichiura*, *Trichocephalus dispar*, or whip worm, does not appear to cause pathological symptoms. It has, however, been known to enter the appendix, and has even been blamed for producing attacks of inflammation in that organ. Its habitat is the cæcum. Drugs have little or no effect upon it. Thymol and turpentine are sometimes given and do in some instances cause its expulsion.

Prophylaxis.—All water should be boiled or filtered through a modern filter. Watercress, salads and other raw vegetables are dangerous if the areas from which they are gathered are liable to contamination with human sewage.

G. C. L.

Uncinariasis. See *Ankylostomiasis.*

Ankylostomiasis.—The treatment is practically the same whether the patient is infected with *Ankylostomum duodenale* or with *Necator americanus*, in which case the Americans call the disease Uncinariasis. Attention should be drawn to the difference between the worm-carriers who have no symptoms of disease and the worm-sick, who are in obvious need of treatment. The important aims are to expel the worms from the small intestines, to treat the anæmia and also any concurrent disease which is present.

Three vermifuges are in use—

1. Eucalyptus oil 30 min., Chloroform 45 min., Castor oil $1\frac{1}{4}$ oz., is the dose invented by Dr. Hermann of Mons, Belgium. The following routine is useful: at 6 p.m. give a saline purge, and let the patient fast all night; at 7 a.m. give half the above dose, and at 7.30 a.m. the remainder; give no food until the bowels act, when the motions must be carefully washed to see how many worms have been expelled. The treatment may be repeated in three days' time. For children and for feeble, very anæmic patients it is wiser to divide the original dose into three parts, giving one-third part every half hour. This method has been employed in Egypt, but is not popular in Porto Rico, where the physicians find it costly, disagreeable and even dangerous.

2. Thymol has been much used since its introduction by Bozzolo in 1880. It used to be given in enormous doses of 90 gr. in a morning within four hours, but I have proved that it is not necessary to give an adult any quantity larger than 15 gr. overnight and 15 gr. the next morning, provided the stomach is empty and kept so until a succeeding saline purge has acted. The remedy can be repeated in a week and at least on three or more different occasions until eggs can no longer be discovered in the fæces. Children take half doses very well. Large doses of thymol produce poisonous symptoms not unlike those caused by carbolic acid. Dangerous collapse and even death used to occur after its indiscriminate use with old people, but are seldom met with now that we have learnt not to give alcohol with it. Besides alcohol, ether, chloroform, glycerine, turpentine and oils should not be given at the same time, and contra-indications to thymol are great weakness, very low temperature, age above 60, fatty heart or kidney disease. Thymol is still the favourite drug in some tropical countries and is decidedly better than β-naphthol for out-patients because the latter requires more care in previous starvation.

3. β-naphthol is extensively used in Porto Rico and Natal. It should be as fresh as possible and must be kept in a cool place. The routine method is to give overnight Mag. Sulph. $\frac{1}{2}$ oz. and no food; next morning give

β-naphthol 30 gr.
Mucilag. Tragacanth ʒ i
Ag. Menth. Pip. ʒv at 6 a.m.;

repeat this dose at 8 a.m. and again at 10 a.m., and at 12 noon give Mag. Sulph. 6 dr. Women should be given only 25 gr. of β-naphthol, and children 5 gr. or more, according to their age. Oil of chenopodium in 15 min. doses has lately been praised in Sumatra and the Malay States.

Extract of male fern is sometimes given, but it is a very feeble expeller of this worm, even in toxic doses.

Good food, including meat, is essential between the doses of any vermifuge. The anæmia is most quickly cured by large doses of sulphate of iron, say 8 gr. three times a day, in a mixture of glycerine and water. Bone marrow is also useful, and feeble individuals will require digitalis and strychnine.

Prevention.—Cleanliness, enforced latrines or portable pails, if in mines are very important. Disinfect, burn or bury fæces. Examine miners and coolies before they are engaged. Insist on coolies wearing shoes or having their feet and legs tarred before working in soiled, damp earth. Keep hands from contact with mouth while at work. If mines must be sprinkled with water to allay dust, add salt (2 per cent.) to the water.

Ankylostomiasis ceased to be an industrial inconvenience in the Cornwall mines after the provision and control of sanitary pails, which could easily be brought to the surface, emptied and cleaned. The eggs can be destroyed by (1) burying in the ground eighteen inches deep, provided there is no running water there; (2) exposure to dry, sun-heat for one day; (3) mixing fæces with an equal quantity of Sol. Hyd. Perchlor. 1 in 200; or (4) exposure to artificial heat 113° F. or to freezing point. F. M. S.

Ascariasis.—Santonin is the anthelmintic for the *Ascaris lumbricoides.* Its toxic effect on these parasites is very marked, and after a few doses they soon come away. The drug is usually administered together with a purgative. Castor oil seems to help its action, and therefore may be employed. An emulsion of the two may be made or the santonin may be given at night, and the castor oil the following morning. The adult dose is 5 gr., that for a child of two to four, 2 gr.; six to ten, 3 gr.; twelve to eighteen, 4 gr. The dose is generally repeated three times, either on successive nights or on alternate days. Sometimes coloured vision is complained of after taking it. This soon passes off. Excessive doses may produce serious symptoms; therefore they should be avoided.

Prophylaxis.—As for the *Trichuris trichiura.* G. C. L.

Oxyuriasis.—*Oxyuris vermicularis*, the threadworm. The parasite is common in children. Its presence about the anus causes irritation and itching which causes the child to scratch the part. After this the fingers are probably sucked and so the eggs are carried back to the mouth, thus causing a re-infection. This must be borne in mind during the treatment, which is applied by means of anthelmintic enemata. Efficient drugs for these are as follows: Salt and water 1 oz. to the pint), quassia infusion, vinegar, alcohol and water or lime water. These, of course, only kill the local worms about the rectum and do not effect the high-up ones in the cæcum and colon. Granted that re-infection and auto-inoculation is prevented, however, the infection may be expected to die out in about a month on such a line of treatment.

Prophylaxis.—A pure water supply, and as for the *Trichuris.* During infection the prevention of auto-inoculation. G. C. L.

DISEASES DUE TO ARTHROPODS

Acarina (ticks).—Apart from inoculating infectious germs (spirochætes, etc.) into one, the bite of the tick *per se* may cause inflammation and septic trouble. Once the parasites are attached they should not be roughly pulled off, as if so the head will be left behind. Soaking them in oil or paraffin will generally make them loose their hold of their own accord.

Siphunculata (lice).—These parasites have recently been shown to be the vectors of the germ of typhus fever and also of the *Spirochaudinnia recurrentis*, the cause of relapsing fever.

Treatment.—Burn all infected clothing or have clothes, bedding, etc., disinfected by steam heat. Stavesacre ointment and kerosene are both good for the *P. capitis ;* hydrargyrum ammoniatum ointment for *P. pubis.* Carbolic lotion may be used for relieving the itching and disinfecting the skin.

Hemiptera (bugs).—*Prevention.*—Use iron bedsteads. Sulphur fumigations to be used where houses are infected.

Diptera (mosquitoes or flies).—Poisoned wounds may follow the punctures of these insects. By washing the parts bitten with carbolic lotion 1 in 20 these results may largely be avoided. When travelling, especially in the tropics, a good plan is to go provided with a small phial of pure carbolic acid. By sharpening the end of a match and dipping it in this a small quantity of the acid can easily be applied to the puncture of ticks and other insects.

Siphonaptera (fleas).—*Prevention.*—Cleanliness. Dogs, if admitted to houses, to be washed in Jeyes' fluid or other disinfectants frequently. Pyrethrum powders also useful. Destroy breeding-grounds where possible by soaking in boiling water frequently. G. C. L.

TREATMENT OF THE INTOXICATIONS

METALLIC POISONING, CARBONIC ACID GAS, ETC.

Metallic Poisoning

A. Acute Poisoning.

Requisites.—The following are commonly required in the treatment of the acute cases of poisoning, which are discussed in this article—

1. Stomach tube.—A soft rubber œsophageal tube 24 to 36 inches in length, connected by a piece of glass tube to a rubber tubing 18 inches long, which is attached to a glass funnel. Two sizes should be kept. No pump should be used.
2. Higginson's enema syringe.
3. Emetics.—Tin of mustard; zinc sulphate, in powders containing 30 gr.

4. Hypodermic syringe.
5. Hypodermic injections.—Morphine sulphate; pure ether; strychnine sulphate.
6. Stimulants.—Brandy; ether; tin of coffee.
7. Antidotes.—Ammonia; calcined magnesia, 4 oz.; glycerine of tannic acid, 2 oz.; magnesium sulphate, 4 oz.; potassium permanganate, 2 dr.; tincture of perchloride of iron, 4 oz.
8. Litmus paper.
9. Vinegar; common salt; washing soda.

General Principles of Treatment.—There are few general principles on which the treatment of any case of poisoning by the mouth is based.

These principles have the following objects—

1. To remove the contents of the stomach.
2. To render inert the poison remaining in the stomach and the system.
3. To support the general strength of the individual.

1. The contents of the stomach may be removed either by active washing of the organ after passage of a stomach tube, or by an emetic.

(1) *The Stomach Tube.*—The passage of this is contra-indicated where the poison is a strong acid or alkali taken in concentrated form, owing to the risk of perforating the injured wall of the stomach.

It is important that the tube be passed with as little disturbance to the patient as possible. The following method should be adopted. If possible the patient should not be lying on the floor but on a bed or table. The head is placed in its natural position, if anything a little bent forward, but certainly not bent back. The mouth is opened only sufficiently wide to allow the insertion of the forefinger and the tube. A gag, such as a cork, should be employed if there is any risk of the jaws being forcibly closed by the patient. The tube is warmed in hot water and may be lightly covered with sweet oil for 18 inches. Oil is preferable to glycerine. The forefinger of one hand is placed in the mouth and the tube guided along it to the back of the pharynx. The forefinger is then withdrawn and the tube pushed gently down. It should be passed 16 to 18 inches or until the resistance of the stomach wall is felt. No force is necessary at any point but a gentle push has usually to be given as the tube passes over the cricoid.

When the tube is in the stomach no attempt to withdraw the contents must be made until water or fluid has been poured in. Omission to take this precaution may result in serious injury to the wall. Half a pint at least should be allowed to flow in and the funnel is then held down below the level of the patient before the fluid has entirely run out of it. In this way syphon action is ensured. If no fluid is returned, the tube may be gently "milked" by the fingers so as to cause slight suction. If this fails more water can safely be allowed to run in, and the funnel then depressed again. No difficulty is usually experienced in emptying the stomach in such a manner. The washing should be repeated several times. After the first washing at least a pint of fluid should be allowed to flow in on each occasion.

(2) *Emetics.*—Certain emetics are easily prepared.

(*a*) Mustard and water.—A tablespoonful of household mustard stirred in half a pint of tepid water. This is the only emetic which has a stimulating effect. It can safely be administered by any one.

(*b*) Salt and water.—Two tablespoonfuls of common salt stirred in half a pint of tepid water.

(*c*) Zinc sulphate.—Half a drachm in half a pint of water. This should be repeated in half an hour if vomiting has not occurred.

(*d*) Apomorphine.—This should be given by hypodermic injection in doses of $\frac{1}{10}$ gr.

These emetics are not mutually exclusive, and two or more may be given consecutively. This is especially recommended in the case of the last two. Apomorphine is very depressing if vomiting does not occur, and an emetic of mustard by the mouth should also be given. Zinc sulphate is a very reliable emetic, but has some irritant action on the stomach if it fails. When once it has been given it becomes important that vomiting should occur. If this is delayed give mustard and water, and repeat the zinc sulphate in half an hour. It may be noted here that it is often extremely difficult to cause vomiting in cases of carbolic acid poisoning, and in view of the importance of emptying the stomach, the tube should be passed at once.

2. *Render Inert the Poison Remaining in the Stomach.*—The principle involved is the addition of a substance which will combine chemically with the poison in the stomach to form a harmless, or comparatively harmless, compound.

The compound formed is rarely completely non-toxic, and in most cases the stomach must be subsequently emptied as soon as possible.

The treatment in this manner of certain groups of poisons will be considered here—

(a) *Acids.*—The principle is the administration of alkalies or certain salts in order to neutralise the acids. The best substance is undoubtedly calcined magnesia. In an emergency soap and water, or the scraping from a plastered wall or ceiling may be employed. Chalk or sodium bicarbonate neutralises acid, but in doing so carbonic gas is evolved, and if the stomach has been seriously injured by a

powerful acid the distension by the gas may lead to its rupture. These methods should, however, be employed in the absence of a supply of magnesia. If nothing is available, large draughts of water help to dilute the acid.

The substances to which these methods especially apply are hydrochloric, nitric and sulphuric acid.

(b) *Alkalies.*—This includes caustic potash, caustic soda and lime. The administration of acids causes neutralisation. The best acid is dilute acetic acid which may be given as vinegar. It is inadvisable to administer diluted solutions of the stronger acids.

(c) *Protoplasmic Poisons.*—The salts of certain heavy metals, especially copper, silver, mercury and zinc, and also sugar of lead, form compounds with albumin. When the salts of these metals are taken, they act on the mucous membrane of the alimentary canal. On filling the stomach with an albuminous solution the metal will form a combination with this albumin. This is done by giving the patient the white of eggs beaten up in water. The compounds of metal and albumin are themselves toxic to some extent, and the stomach must be washed out as soon as possible afterwards. This method should be employed when these substances have been taken, except in the case of silver nitrate, for which common salt is an effective remedy.

Apart from these groups the particular method to be adopted varies for different poisons, and will be found under the respective substance in the alphabetical list below.

3. *Support the General Strength.*—There is a great tendency to collapse even when the acute symptoms appear to have subsided.

The patient should be wrapped in warm blankets with hot-water bottles. Care must be taken that no pressure is put on a tender epigastrium.

The pain and gastro-enteritis following the corrosive and severe irritant poisons lead to extreme shock. To combat this give a hypodermic injection of morphine sulphate $\frac{1}{3}$ gr., but the immediate symptoms should be allowed to subside before the injection is made.

Stimulants are usually necessary. Often it is impossible or useless to give anything by the mouth as the stomach tube may be in employment or the stomach too much injured. The stimulants used must be such as act rapidly. Thus—

(*a*) Hypodermic injections of pure ether 30–60 min.; or of brandy 1 to 2 dr.

(*b*) Enema of coffee and brandy: 3 oz. of brandy made up to 1 pint with strong coffee.

(*c*) By the mouth: sal volatile 2 dr. in 2 oz. of water, or brandy 2 oz. in water.

Diet needs little consideration, for when gastro-enteritis is marked the alimentary canal is not in a condition for digestion and absorption, and the patient has to be tided over the acute stages by stimulants. Milk should then be given and be the sole diet until the acute symptoms subside.

Water must never be withheld and the patient should be allowed to drink freely. The withdrawal of fluid from the body by vomiting and purging is often difficult to deal with. If the skin becomes inelastic, a long rectal tube should be passed and tepid (not hot) water allowed to run in slowly by syphon action from a height of 12 to 18 inches. For this the patient is turned on the left side with the buttocks slightly raised by placing a pillow below. A pint at a time should be run in if possible.

Purging should not be checked in the earlier stages, but if it continue starch and opium enemata should be given.

The patient must not be left alone. The opportunity may be seized to repeat the dose or attempt an alternative method if suicidal, and in any case the possibility of rapid collapse is present in most forms of acute poisoning.

Treatment of Cases where the Poison is not known.—It may happen that a summons comes to a case where the causal agent is not known. The following rough outline of signs and symptoms may be of assistance in diagnosis and treatment—

1. Vomiting.
   - Strong acids (acid vomit) and alkalies (alkaline vomit).
   - Arsenic.
   - Antimony.
   - Corrosive sublimate.
   - Phosphorus.
   - Silver nitrate.
2. Vomiting and rapid purging.
   - Arsenic.
   - Antimony.
   - Corrosive sublimate.
   - Phosphorus.
3. Coma.
   - Gas poisoning.
   - Opium.
   - Alcohol.
   - Veronal.
   - Overdose of any "Sedative" drug.
4. Collapse.
   - Carbolic acid (without vomiting).
   - Oxalic acid.
   - Prussic acid.
   - Following vomiting or purging from any cause.

5. Muscular spasms.
    Strychnine.
    Severe pain from acute irritant poisons may lead to powerful voluntary contraction of muscles.
6. Delirium.
    Alcohol (unpleasant).
    Atropine (pleasant).
7. Pupils contracted.
    Opium.
8. Pupils widely dilated.
    Alcohol.
    Opium (when moribund).
9. Mouth discoloured.
    Carbolic acid.
    Oxalic acid.
    Strong acids and alkalies.
10. Abdominal pain.
    May be due to any of the agents which lead to vomiting or purging even in the absence of these symptoms.

The treatment in these uncertain circumstances should follow the lines given under *General Principles of Treatment* so far as possible.

Firstly (and most important), the stomach tube should be passed and the stomach washed out carefully. The contents may give a hint of the cause by their reaction to litmus, smell, etc. A pint of water should be left in the stomach. Secondly, stimulants should be given, an enema of brandy and coffee being specially serviceable. Morphia must not be given to ease pain. The patient must be put to bed, and kept completely at rest until all risk of secondary collapse and recurrence of symptoms has passed.

Treatment of Acute Poisoning by Various Agents. *Note.*—Where several alternatives are given, the nearest remedy should be used. They are arranged in the order of efficiency. Hypodermic injections are given in doses for an adult. Antidotes by the mouth depend on the amount and concentration of the poison and not on the age and size of the patient.

Acids (Strong). *Symptoms.* — Instantaneous burning pain from lips to abdomen. Difficulty in speaking and swallowing. Vomiting of highly acid fluid containing altered blood or shreds of mucous membrane. No diarrhœa. Extreme collapse. Subnormal temperature. Mind remains clear. Retention or even suppression of urine.

Treatment.—Emetics unnecessary. Stomach tube not to be used in cases of nitric and sulphuric acid. For other acids the tube should be used with care.

Give calcined magnesia $\frac{1}{2}$ oz. to a tumbler of water; or wall-plaster, chalk, or washing soda stirred in water; or large draughts of soap and water. With stomach tube use these for washing. Wrap in warm blankets with hot-water bottles. Next give olive oil 4 oz. in a pint of water; white of eggs (four) and water; or milk. Inject hypodermically morphine sulphate $\frac{1}{3}$ gr. Rupture of the stomach may necessitate operation. Passage of a catheter may become necessary owing to retention of urine.

Alkalies (Strong). *Symptoms.*—Instantaneous onset. Resemble those of strong *acid* poisoning, but purging is common. The vomit is alkaline.

Treatment.—Stomach tube not to be used, if patient can swallow. Give freely vinegar, $1\frac{1}{2}$ oz. in a tumbler of water; or lemon juice or citric acid in water; or acetic acid well diluted or large draughts of water. With stomach tube use these for washing also.

Next give *olive oil*, 4 oz. in a pint of water; or white of eggs (four) and water; or milk.

Inject hypodermically morphine sulphate $\frac{1}{3}$ gr.

Ammonia. *Symptoms.*—Burning pain with marked sensation of suffocation.

Treatment.—Stomach tube usually necessary as patient cannot swallow. Vinegar. Olive oil. Morphine (*vide* Alkalies). Tracheotomy may be necessary owing to œdema of glottis.

Antimony. Fatal dose varies greatly.

Symptoms.—Onset in $\frac{1}{4}$ to $\frac{1}{2}$ hour; may be delayed longer. Gastro-enteritis, vomiting especially marked. The vomiting may empty the stomach completely, and life should never be despaired of even after enormous quantities of tartar emetic. Symptoms resemble arsenic poisoning and cholera.

Treatment.—If vomiting has not occurred, use stomach tube and emetics with large draughts of tepid water. Encourage vomiting.

Give glycerine of tannic acid, 2 dr. in a tumbler of water, or tannic acid, $\frac{1}{2}$ dr. in a tumbler of water, or large drinks of strong coffee or tea. If vomited repeat each time. (Antimony forms an insoluble compound with tannic acid.)

Wrap in warm blankets with hot-water bottles to the feet. As vomiting subsides, give white of four eggs in water or milk. Inject ether 30 min., hypodermically, or brandy and coffee enema; repeat at short intervals.

Rectal injections of saline if possible. Later, when acute symptoms have subsided, inject morphine sulphate $\frac{1}{3}$ gr. hypodermically to relieve pain.

Tendency to collapse is usually marked.

Aqua Fortis.—Synonym for nitric acid.

Arsenic.—Fatal dose, 2–3 gr.

Symptoms.—Resemble antimony poisoning.

Treatment.—Stomach tube. The stomach must be thoroughly and repeatedly washed out. Emetics in absence of stomach tube. Give freshly precipitated hydrated ferric oxide, prepared thus—

Place in a tumbler of water an ounce of tincture or solution of perchloride of iron, and add two tablespoonfuls of washing soda or *dilute* ammonia. Filter the bulky precipitate through a handkerchief and dissolve it in a tumbler of hot water. Give in large quantities, frequently repeated. If this is not available give magnesia or olive oil or castor oil frequently and in large amounts.

As vomiting subsides, give white of four eggs in water or milk. Wrap in warm blankets with hot-water bottles to feet. Give stimulants freely. Inject ether 30 min. hypodermically or brandy and coffee enema; or brandy 1 dr. hypodermically; or brandy by the mouth. Repeat frequently.

When acute symptoms have subsided, inject morphine $\frac{1}{3}$ gr. hypodermically.

Barium Salts. *Symptoms.*—Gastro-enteritis.

Treatment.—Stomach tube or emetics. Give sulphates in some form (in order to convert barium into the insoluble sulphate) and then wash out stomach, thus: Sodium sulphate (Glauber's salts), 1 oz. doses in water, or magnesium sulphate (Epsom salts) 1 oz. doses in water. Wrap in warm blankets with hot-water bottles. Give stimulants. When acute symptoms have subsided inject morphine $\frac{1}{3}$ gr. hypodermically if much pain.

Bichromate of Potash. *Symptoms.*—Gastro-enteritis. Powerful irritant. Mouth and lips stained yellow.

Treatment.—Stomach tube or emetics. Give magnesium carbonate, or chalk, $\frac{1}{2}$ oz. in half a pint of milk. With stomach tube use this for washing also. Then white of four eggs in water. Warmth. Stimulants. Inject morphine $\frac{1}{3}$ gr. hypodermically if much pain.

Carbolic Acid. *Symptoms.*—On swallowing a burning sensation is felt but the anæsthetic action prevents subsequent pain. This usually also prevents vomiting even with emetics, though occasionally it is profuse. Carbolic acid is often taken in large amounts, is rapidly absorbed and acts on nervous centres. Consequently there is rapid onset of unconsciousness with collapse. The smell of the breath is often characteristic, and there may be white or brown patches where the acid has been in contact. After consciousness is regained, *rapid collapse and death may still occur.*

Treatment.—Carbolic acid acts with extreme rapidity and no time must be lost. Stomach tube carefully, wash stomach repeatedly with magnesium sulphate (Epsom salts) or sodium sulphate (Glauber's salts), 1 oz. to a pint of warm water. Use large quantities, continue until no smell of carbolic acid, leave a pint in stomach. Or use saccharated lime water, one part to three of water. If tube not available, give above solutions to drink.

Apply warmth to body, warm blankets, hot-water bottles or friction. Artificial respiration if necessary. Give stimulants freely, brandy by rectum, and ether 30–60 min. hypodermically. Later give white of eggs in water freely, or milk, and injections of saline by rectum. Watch carefully lest collapse occurs after recovery of consciousness. If pulse is feeble, give strychnine $\frac{1}{30}$ gr. hypodermically.

Carbonic Acid Gas (CO_2). *Symptoms.*—Heaviness and throbbing in head. Progressive loss of muscular power. Insensibility. Lividity.

Treatment.—(CO_2 is heavier than air and accumulates near the floor.) Fresh air. Artificial respiration (sixteen to the minute), not to be stopped for any reason, and not to be abandoned for several hours. Inhalation of oxygen, using Leonard Hill's mask or holding jet close to mouth. Friction, warmth to extremities. Occasional inhalation of ammonia. Alternate hot and cold douches to chest. Strong coffee enema (1 pint). Inject ether, 30 min. hypodermically, or brandy.

Carbon Monoxide (CO). *Symptoms.*—Rapid weakness of mental and muscular power. Insensibility.

Treatment.—*Vide* Carbonic Acid Gas.

Caustic Potash. }
Caustic Soda. } *Vide* Alkalies.

Chlorate of Potash.—Emetics. Stomach tube.

Coal Gas. *Vide* Carbonic Acid Gas.

Copper Salts. *Symptoms.*—Metallic taste, gastro-enteritis, collapse.

Treatment.—First, large quantities of white of eggs and milk. Then stomach tube (tepid water) or emetics. Copious drinks of tepid water. When acute symptoms subside, inject morphine $\frac{1}{2}$ gr. hypodermically.

Corrosive Sublimate. *Symptoms.*—Metallic taste, gastro-enteritis, collapse.

Treatment.—First give large quantities of white of eggs in water. Then stomach tube and wash with water, or give emetics. (Mercury forms an albuminate which is toxic and must be removed at once.) Leave some white of egg in stomach. Warm blankets and hot-water bottles. Stimulants. Later inject morphine $\frac{1}{3}$ gr. hypodermically.

Cyanide of Potassium. *Symptoms.*—Onset in one to two minutes. Insensibility. Respirations slow and irregular. Pulse fails. Breath may smell of almonds.

Treatment.—Artificial respiration. Stomach tube or emetics, or large draughts of water. Stimulants. Inject ether 30 min. subcutaneously, and repeat in a few minutes. Inhalation of

ammonia on a handkerchief. Alternate douches of hot and cold water on the chest. The following may be tried as a chemical antidote, but not at the expense of preceding measures: ferrous sulphate 10 gr. in 5 oz. of water, followed by magnesium carbonate 1 dr. in a little water.

Fly Papers. *Vide* Arsenic.

Hydrocyanic Acid. *Vide* Cyanide of Potassium.

Hydrochloric Acid. *Symptoms.—Vide* Acids.

Treatment.—Give calcined magnesia $\frac{1}{2}$ oz. in a tumbler of water, or wall-plaster, chalk, washing soda, well-diluted ammonia, or well-diluted sal volatile in water, or large draughts of soap and water. Repeat if vomited. Wrap in warm blankets with hot-water bottles. Give white of eggs in water or olive oil, 4 oz. in a pint of water, or milk. When acute symptoms subside, inject morphine $\frac{1}{3}$ gr. hypodermically.

Lead Salts. *Symptoms.*—Metallic taste. Colic. Thirst.

Treatment.—Stomach tube or emetics. Give magnesium sulphate (Epsom salts) $\frac{1}{2}$ oz., or sodium sulphate (Glauber's salts) $\frac{1}{2}$ oz., or dilute sulphuric acid $\frac{1}{2}$ dr. in a tumbler of water. Next milk or white of eggs in water. Warmth to abdomen. Inject morphine $\frac{1}{3}$ gr. hypodermically if much pain.

Lunar Caustic. *Vide* Silver Nitrate.

Mercury Salts. *Vide* Corrosive Sublimate.

Muriatic Acid. *Vide* Hydrochloric Acid.

Nitric Acid. *Symptoms.—Vide* Acids.

Treatment.—Give calcined magnesia $\frac{1}{2}$ oz. in a tumbler of water, or chalk, washing soda, wall-plaster, well-diluted ammonia; well-diluted sal volatile, or soap and water in large quantities. Repeat if vomited. Wrap in warm blankets with hot-water bottles. Next give olive oil, 4 oz. in a pint of water, or white of eggs in water or milk. When acute symptoms subside, inject morphine $\frac{1}{3}$ gr. hypodermically. If larynx affected, tracheotomy. Do not pass stomach tube if patient can swallow or is vomiting, but if not, pass tube in preference to doing nothing. The possibility of perforation of the stomach wall must be remembered.

Oxalic Acid. *Symptoms.*—Onset and progress of symptoms very rapid. Acid taste. Pain in stomach. Vomiting. Rapid collapse and cardiac failure from action after absorption.

Treatment. Give saccharated lime water $\frac{1}{2}$ oz. in 2 oz. of water, or chalk or wall-plaster in water in large amounts, or lime water. If vomiting has not occurred, pass stomach tube with care, and wash with lime water. Stimulants. Ether 30 min. hypodermically, or brandy. Repeat saccharated lime water half hourly for six doses. Give milk freely.

Do not give sodium and potassium salts (*e. g.* soap, sodium carbonate, washing soda). The compounds with oxalic acid are very poisonous.

Perchloride of Mercury. *Vide* Corrosive Sublimate.

Phosphorus. *Symptoms.*—May be a garlicky taste. Latent period of $\frac{1}{4}$–2 hours or more. Then garlicky eructations. Luminous vomiting. Purging. Collapse. Death or recovery from these symptoms. A few days later secondary symptoms of acidosis: jaundice, vomiting and acetonuria.

Treatment.—Primary stage. Stomach tube or emetics. Wash stomach with potassium permanganate 1 per cent. solution, or sanitas (or water, if others not available). Leave some in stomach. Then give these to drink: potassium permanganate 1 per cent. solution diluted with three times as much water. Later give magnesium sulphate, $\frac{1}{2}$ oz. in 4 oz. of water. Also milk or white of egg in water. When these symptoms subside, give alkalies to prevent secondary stage: sodium bicarbonate 1 dr. four hourly. Also sugar and water frequently. (1 oz. of sugar four times a day.) Continue for five days at least.

Potash. *Vide* Caustic Potash.

Potassium Chlorate. *Vide* Chlorate of Potassium.

Prussic Acid. *Vide* Hydrocyanic Acid.

Rat Pastes.—"Rough on Rats," and Simpson's contain arsenic. Roth and Ringeisen's contain arsenic and phosphorus.

Salts of Lemon.
Salts of Sorrel. } Synonym for potassium binoxalate. For treatment *vide* Oxalic Acid.

Sewer Gas.—Treatment as for Carbonic Acid Gas.

Silver Nitrate. *Symptoms.*—Gastro-enteritis. Vomit may contain white flakes turning black on exposure to light.

Treatment.—Common salt, two tablespoonfuls in a tumbler of water. Repeat after vomiting. Then emetic of mustard. White of eggs in water in large quantities.

Soda. *Vide* Caustic Soda.

Spirits of Salts. *Vide* Hydrochloric Acid.

Sugar of Lead. *Vide* Lead.

Sulphuric Acid (Swallowed). *Symptoms.—Vide* Acids.

Treatment.—Large draughts of soap and water. Calcined magnesia $\frac{1}{2}$ oz. in 5 oz. of water, or wall-plaster, chalk, washing soda, sodium bicarbonate in water, or water alone if nothing else available. Give the nearest of these before looking for anything else. Repeat after vomiting. Later give olive oil, 4 oz. in a pint of water, or white of eggs in water, or milk. Wrap in warm blankets with hot-water bottles. Inject morphine $\frac{1}{2}$ gr. hypodermically. The possibility of perforation of the stomach wall must be remembered.

Sulphuric Acid (Thrown).—Wipe off the acid and bathe with soap and water, or water con-

taining soda or bicarbonate of soda. If the eyes are involved wash them gently with water and then with a lotion of sodium bicarbonate and water (5 gr. to the ounce). Then drop in a few drops of castor or olive oil. Keep quietly in bed. Give stimulants, especially brandy. Then inject morphine sulphate ⅓ gr. hypodermically.

Tartar Emetic. *Vide* Antimony.

Vermin Killers.—"Rough on Rats," and Simpson's contain arsenic. Roth and Ringeisen's contain phosphorus and arsenic. Battle's and Butler's contain strychnine.

Vitriol. *Vide* Sulphuric Acid.

Water Gas. *Vide* Carbon Monoxide.

Weed Killers. *Vide* Arsenic.

White Precipitate. *Vide* Corrosive Sublimate.

White Vitriol. *Vide* Zinc.

Zinc Salts. *Symptoms.*—Profuse vomiting. Gastro-enteritis.

Treatment.—White of eggs and milk. Sodium carbonate or washing soda in large quantities of warm water. Strong tea. Inject morphine ⅓ gr. hypodermically, when acute symptoms have passed.

For other poisons see *Pharmacological* section under respective drugs.

B. Chronic Poisoning

The common chronic forms of metallic poisoning are due to arsenic, lead, mercury and, rarely, phosphorus. "Brass-founder's ague" is due either to copper or arsenic. In all cases the treatment is removal from the cause, and general treatment for the symptoms.

Arsenic.—The disturbance of the alimentary canal must be corrected, for which Mist. Cretæ. may be employed. A light diet without alcohol should be given. The mucous membranes of the eye and mouth may be inflamed or ulcerated, in which case they should be bathed with boracic acid lotion. Tonics and a full diet should be given as soon as the intestinal irritation subsides. Arsenical paralysis needs rest in bed, with the administration of strychnine and the employment of massage and electricity. Pigmentation of the skin needs no treatment.

Lead.—Three main sets of symptoms occur in chronic lead poisoning.

1. *Attacks of Colic and Constipation.*—To ease the pain in a paroxysm hot fomentations should be applied to the abdomen, and tincture of opium, 20 min., given by the mouth. The bowels must be opened at once by an enema of olive oil or hot water. Then an ounce of castor oil by the mouth. Subsequently belladonna and sulphates should be administered.

℞ Magnesii Sulphatis, ʒ ½
Acidi Sulphuris Dil., ♏ x
Tincturæ Belladonnæ, ♏ v
Aquæ Menth. Pip., ad. ℥ i

To be taken three times a day until the colic has subsided and the bowels are well opened. The belladonna should then be omitted and the sulphates continued. The diet should be light as long as the intestinal symptoms are present.

2. *Lead Palsy.*—In the great majority of instances this involves the extensors of the wrists. When severe the hands must be supported by splints or slings. Massage and electricity should be employed and strychnine administered.

3. *Lead Encephalopathy.*—These cases may closely simulate cerebral tumours. The patient must be kept in bed and sulphates administered. In all forms of lead poisoning tonics are necessary, especially iron: thus ferrous sulphate 3 gr. may be added to the sulphate mixture. Potassium iodide, to assist the elimination of lead from the tissues, should not be given while acute symptoms persist, but may then be used in 5 gr. doses three times a day.

Mercury.—With very small doses of mercury gingivitis and salivation may occur. The administration must be stopped immediately. Mouth-washes, such as myrrh and borax, must be used frequently. If the alimentary tract is irritated, Pulvis Cretæ Aromaticæ 30 gr. three times a day is useful. Constipation must be avoided. Tonics should be given when the acute symptoms subside, and a full diet.

H. L. T.

ALCOHOLISM AND OTHER DRUG HABITS

All the habit-forming drugs referred to in this article exhibit certain effects in common—

1. In the early stages of the habit they give rise to *euphoria*, that is, a temporary sense of comfort and well-being; this constitutes the essential motive of indulgence. Euphoria is a brain effect and varies in character and degree with the drug and the dose of the drug.

2. Taken regularly they establish *tolerance*—that is, a condition in which they cease to produce euphoria and other physiological effects unless given in large and increasing doses. Such *acquired* tolerance arises most readily through the use of frequent, small, but progressively increasing doses, each of which is but just sufficient to cause moderate euphoria. The steady spirit drinker, especially the secret drinker, offers the most familiar example.

3. Acquired tolerance, if at all marked, involves in the great majority of cases *intolerance of sudden withdrawal*. That is to say, the sudden withdrawal of the drug, unless compensated or obscured in some way, is followed by mental misery and definite physical symptoms. Such *sudden abstinence phenomena* are fairly distinctive for each individual drug: in character they are

for the most part the opposite of the mental and physical symptoms which constitute the special euphoria conferred by the drug; and they vary in severity with the degree of tolerance acquired and with the suddenness of withdrawal. They may be extremely severe, and in some cases have led to insanity and, directly or indirectly, even to death.

4. Following a period of abstinence of doubtful duration, acquired tolerance is *lost*. Doses of the drug previously taken with little effect may then prove disastrous, even fatal.

5. Those who have recovered from any of the drug habits here referred to can never again hope to use the drug in question in moderation. Thenceforward they must consider themselves a class apart in this one respect, namely, that in their case moderate use will inevitably lead to excess: total, and permanent total, abstinence is for them the only course. Furthermore, what is true of the use of the same drug is only slightly less true of the use of any other of the drugs in the series.

All the above five propositions have a distinct bearing on the question of treatment.

Alcoholism

The goal of treatment, then, is the establishment of permanent total abstinence; and the first indication is the withdrawal of alcohol. Now the mode of withdrawal—whether the drug should be carefully *tapered* off or suddenly withheld—will depend on the presence or absence of acquired tolerance. Moreover, when tolerance is present, its degree will determine inversely the rapidity of tapering which is expedient.

Unlike most other drug habits, alcoholism exists in two forms: it may be intermittent—dipsomania, pseudo-dipsomania; or continuous—chronic inebriate alcholism, chronic sober alcoholism.

Intermittent Alcoholism.—In both varieties (dipsomania and pseudo-dipsomania), at least in typical cases, the drinking is short-lived and furious: tolerance has no time to become established. Hence tapering is unnecessary. Not only so, it is actually injurious, greatly increasing the difficulty of managing the case. Every dose of alcohol given, at any rate in all but the last stages of the paroxysm, markedly intensifies the craving, although it may be admitted it affords momentary relief. If, on the other hand, the patient can be kept for one, two or three days (the exact time varying with the case) without any alcohol, all craving ceases, often with remarkable suddenness. But it is impossible in most cases, without having full legal control of the patient, simply to withhold alcohol. Hence, in both private and sanatorium practice, resort must be had to drugs for assistance. Here, fortunately, we have in apomorphine a drug which accurately fits all such emergencies. Indeed, it is not too much to say that without the assistance of apomorphine it would be impossible to carry on with any satisfaction a free sanatorium into which were frequently admitted acute cases of alcoholism.

Apomorphine is always given hypodermically, and the most convenient solution, which should have been made somewhat recently, is 1 in 200. The dosage will vary with the state of the patient. If intoxicated, especially if noisy or violent, a full dose is demanded. In textbooks this is set down at $\frac{1}{10}$ gr., equal to 20 min. of the above solution. But though there is no death recorded, severe collapse is stated to have followed this dose occasionally. Accordingly, for some years 15 min. has been the maximum dose I have used. This is ample, and its effect can only be described as dramatic. Just previously the patient may have been wildly uproarious, even actively homicidal, necessitating several attendants to control him. Yet always within ten minutes, usually within four or five, he is placidly asleep. The first effect of the injection is pallor: the patient becomes suddenly quiet, his muscles relax, and he vomits. Immediately vomiting ceases he is asleep. Sometimes, indeed, he is asleep even before the diaphragmatic spasms have ceased: hence a possible danger of choking unless he is carefully watched for a time. In one case only has 15 min. failed to cause emesis: it has never failed to cause sleep, though used in upwards of 200 cases. The sleep which ensues is at first deep, but within a hour or so becomes light, and the patient is easily roused. It always lasts for a couple of hours: sometimes it endures for seven or eight.

But in any case when he awakes, the patient's mental condition is entirely altered. He may be sober: he is at least quiet and tractable; and, moreover, he is free for the time being from any craving for alcohol. The craving may return, however, and then it is necessary to repeat the injection, it may be several times at intervals of a few hours. These succeeding injections should be quite small, 3 to 6 min. being sufficient. Doses of this size are rarely emetic. There is a little facial pallor, a sensation as of the commencement of sea-sickness, perhaps slight malaise, with a sudden subsidence of the craving for alcohol, followed by a light and short doze.

In addition to quelling each marked recurrence of the dipsomaniac craving by small prompt injections of apomorphine, it is nearly always advisable to administer at bedtime a *full* dose of some more enduring hypnotic: this at any rate for the first night or two after the patient comes under treatment. Usually, perhaps, veronal is most suitable. But sulphonal,

trional, paraldehyde or chloral may be substituted. If the patient has taken hypnotics previously and knows the dose which is for him efficient, it will be expedient not to alter the drug: thus the dangers of under- and over-dosing are avoided.

Continuous Alcoholism.—Practically always in both varieties of this form there is established some degree of tolerance of alcohol. This degree, which of course varies widely, must be first determined with some approach to accuracy. Commonly—almost invariably in sober alcoholism—the patient can say exactly what he takes and when he takes it. But in not a few cases—especially, of course, in inebriate alcoholism—the amount taken cannot be stated or is deliberately concealed, that is, understated. Then it is necessary to institute a short tentative period of abstinence. Very soon, in cases of high tolerance, abstinence symptoms appear. Such are nervousness, restlessness, irritability, muscular tremor on voluntary movement, and insomnia, perhaps also anorexia and nausea. By studying these and the effect upon them of known doses of alcohol, it is easy with a little practice to estimate with sufficient accuracy the degree of tolerance acquired. This may vary from quite small amounts to 20 or 25 fl. oz. of spirits: it is rarely more. And it is only the larger amounts (from 10 fl. oz. upwards) which are of importance clinically.

Having determined the degree of tolerance (which, except in strictly sober alcoholists, does not of necessity coincide with the habitual amount of alcohol taken) tapering should be at once instituted. Quite the most important point is that *no sudden large* reduction should be made *during the first three or four days*. Supposing tolerance to be estimated at 20 fl. oz. of whisky per diem (*i. e.* in the twenty-four hours), the first reduction should be to 18 fl. oz., certainly not less than 17; the next to 16, not below 15; and the next to 13 or 12. A safe rule is to deduct 2 fl. oz. per diem. When, however, the amount has fallen to 4 or 5 fl. oz., further tapering is unnecessary: indeed, many patients themselves suggest final withdrawal at this stage. There is nearly always some albuminuria in chronic alcoholism, and the degree of albuminuria may or may not be an accurate index of the degree of tolerance established. But whether this is so or not, the presence of much albumen certainly increases the necessity for tapering as against sudden withdrawal.

It will be observed that alcohol tapering represents roughly an arithmetical progression: herein differing essentially from morphine tapering, as will be pointed out later.

The tapering process is greatly facilitated by the use of bromide of sodium, given thrice daily in dram doses. In addition it is often, if not usually, advisable to give a special hypnotic at bedtime. The hypnotics used are the same as those recommended in intermittent alcoholism. One great advantage of tapering is that it renders an ordinary full dose of any hypnotic sufficient to ensure a good night's sleep. Under sudden withdrawal, enormous, even dangerous, doses would be necessary in many cases.

Abstinence Phenomena of Chronic Alcoholism.—The minor phenomena have been mentioned: the major include *delirium tremens* and *alcoholic epilepsy*.[1] The treatment of these complications may be considered under the heads of (1) preventive; (2) abortive; and (3) in the actual attack.

The preventive treatment in both complications is that of alcoholic tolerance, and has just been described. Given sufficient time, it should be almost invariably successful as regards delirium tremens. Fits, however, may occasionally occur, since now and then they are apt to arise in quite low degrees of tolerance—degrees which have not seemed to necessitate tapering. Moreover, they are less frequently preceded by minor abstinence phenomena than are attacks of delirium.[2]

The abortive treatment of delirium tremens can be adopted successfully only in the very early stages of the attack, when the mental symptoms are but just commencing. It consists in rapidly making up the deficiency in the alcoholic intake so that the point of tolerance is reached, or nearly so, combined with a full dose of some hypnotic should sleep not quickly follow the alcohol. Subsequently, careful tapering should be practised. Delirium tremens has been aborted also by very large doses of hypnotic drugs without alcohol, and by chloroform anæsthesia. The latter method, however, has proved fatal, nor can the former be said to be free from danger.

The treatment during a fit is that of any major epileptic attack. As regards the developed attack of delirium, it usually suffices to provide adequate, skilled attendants—two at least are always required—and to instruct them not to allow the patient out of their sight for an instant and to see that some fluid nourishment is regularly given. Whether or not alcohol should be allowed is undecided: my own experience

[1] "Both alcoholic epilepsy and delirium tremens depend primarily and remotely upon the acquisition of tolerance of alcohol, and secondly and proximately upon a sudden fall in the accustomed quantity of alcohol circulating in the . . . brain and nervous system."—*On Alcoholism*, Francis Hare, 1912, p. 154.

[2] When they are so preceded it is highly probable that delirium also is impending—that the former is merely a part of the latter.—*On Alcoholism*, Francis Hare, 1912, p. 156.

is that, though it modifies the severity of the delirium, it defers convalescence. In exceptional cases—when the delirium is prolonged beyond three full days, when the temperature rises to 101° F. or more, or when there are signs of circulatory failure—it seems essential to procure sleep by means of drugs. Hyoscine seems most likely to succeed. Commencing with $\frac{1}{150}$ gr. I have given up to $\frac{1}{80}$ gr. every six hours. The usual result is an hour or two of rather disturbed sleep following each injection.

Reference may here be made to mania à potu, pathological or maniacal drunkenness, a condition which, though sometimes confused with delirium tremens, differs essentially therefrom.[1] The treatment consists merely in a single full dose of apomorphine with confinement to bed during the subsequent sleep. This is practically always completely successful.

Treatment following Complete Withdrawal of Alcohol.—Though, as pointed out, all craving for alcohol rather suddenly ceases a few days after withdrawal, yet such freedom is not necessarily continuous thenceforward. There are recurring days on which the craving is apt to return in some degree : this at any rate in the majority of patients and for a few weeks. Accordingly, the patient should always remain under supervision and treatment for *at least* six weeks in all : often a longer period is advisable. During this time all his habits should be regularised. Regular outdoor exercise short of fatigue, regular well-cooked and well-served meals not too elaborate, at least eight hours' sleep and frequent dogmatic advice short of causing boredom —all these are necessary. The advice tendered should allow him no escape from the conclusion that total, and permanent total, abstinence from even minute quantities of alcohol is for him essential.

It should be pointed out that the taking of one small alcoholic drink re-creates the craving and leads inevitably sooner or later—sooner in the vast majority of cases—to frank relapse into alcoholism : that consequently the first alcoholic drink constitutes the relapse and immediately entails a new course of treatment even if a very short one : so the patient may start afresh with an absolutely clean sheet. The regular administration of such advice should be regarded as an item in the course of treatment, not less essential than the regular exhibition of medicines by the mouth and by the hypodermic needle. It constitutes, indeed, treatment by suggestion and is, in my experience, at least equal in efficiency to treatment by hypnotic suggestion. But here there is an important proviso. Always averse from facing unwelcome facts, the patient will inevitably discount advice tendered him by one who has acquired the reputation of being an extremist in temperance matters. Should the physician be himself convinced that abstinence is the only true temperance for the whole of the human race, he will be well-advised to conceal his opinion from his alcoholic patient. On this point there is no room for doubt.

The patient should regard himself as an individual with one special weak point to which he will always have to live down. This refers, of course, to his inability to indulge moderately in alcohol. It may even be admitted that, consequent on this necessity, he will lose some enjoyment when compared with the ordinary temperate person. But it can be safely insisted that there are numerous compensations which in the aggregate more than out-balance his limitations. Men of means who, on becoming abstainers succeed in acquiring some absorbing hobby usually do well, while for business men and others whose income has to be earned, it is always expedient at the end of their course of treatment to return straightway to their work and commence at once to recover some of the leeway for which their habit has been responsible. Prolonged change of air, holidays of various kinds, trips, *above all sea-trips*, are not only unnecessary but often actively harmful. Of all places in the world a modern passenger steamer is the worst for the ex-alcoholist.

In addition to general hygiene and systematic suggestion, a special course of medication should follow, not precede, the final withdrawal of alcohol. In the sanatorium with which I am connected the drugs in use are strychnine, atropine and red cinchona bark. The former two are given both hypodermically and by the mouth : the last in the form of a tonic. The solutions for hypodermic use are strychnine nitrate 4 gr. to the ounce of distilled water, and atropine sulphate 1 gr. to the ounce. The first injection consists of 2 min. of the strychnine solution with 1 min. of the atropine solution. This is given in the one injection thrice daily immediately after breakfast, lunch and dinner. After a day or so, the dose is raised by the addition of 1 min. of each solution. Every few days similar additions are made until the patient is receiving 7 and 6 mins. respectively of each solution. Larger doses are now rarely used. The maximum dose may be continued for perhaps a week. Subsequently the dosage is reduced by the same steps as it increased, until at the end the patient is receiving 2 min. and 1 min. respectively. The tonic contains

[1] "Mania à potu depends upon intolerance of alcohol, inherent or acquired, and is a direct result of the consumption of alcohol often in quite small quantities; delirium tremens depends upon a tolerance of alcohol which is always acquired, and is a direct result of a sudden inadequacy in the regular supply of alcohol to the blood and nervous system."—*On Alcoholism*, Francis Hare, 1912, p. 129.

strychnine solution 1 min., atropine solution 1 min., concentrated liquor of cinchona (Fletcher) 24 min., concentrated compound liquor of gentian (Fletcher) 8 min., and glycerine 1 dr., in each half-ounce dose. This is given diluted three or five times daily between meals.

Only occasionally have modifications to be made in this medication. Slight muscular twitchings demand a temporary reduction or cessation of the strychnine, and this drug may have to be omitted from the evening injection in some cases of insomnia; there are also some alcoholists in whom strychnine causes extreme irritability and nervousness. The atropine may have to be omitted should there result cutaneous irritation sufficient to prevent sleep, and in rare cases cinchona causes rather severe dyspepsia.

The use of these drugs is purely empirical. I can only express my own belief that their use as above described is of some real assistance in maintaining the freedom from the craving for alcoholic euphoria.

Management of True Dipsomania.—This is the one exception to the rule that alcoholists after withdrawal should remain under supervision and treatment for at least six weeks. The term dipsomania is often applied loosely to any case of severe paroxysmal drinking. But it should be reserved for cases in which the craving for alcohol comes on *in spite of prolonged abstinence.* Such patients usually show distinct premonitory symptoms and the paroxysms occur at more or less regular intervals. These cases are quite rare, and in them there is probably less danger of relapse into drinking during the immediately post-paroxysmal period than at any other time. What is above all necessary in their case is to recognise the commencement of the premonitory stage and bring the patient immediately under supervision and treatment. When this can be done—which unfortunately is not often—a few doses of apomorphine, perhaps reinforced by a single full dose of some more enduring hypnotic at bedtime, will usually succeed in completely preventing or aborting the threatening paroxysm. There is little to be gained by keeping these patients under close observation for more than a fortnight, unless, of course, the duration of the supervision is sufficient to cover several paroxysms, as in treatment in a licensed retreat under the Inebriates' Act.

Morphinism

Possibly because tolerance is so rapidly established, morphinism exists almost solely in the continuous form. Patients are sometimes said to suffer from intermittent or paroxysmal morphinism; but these on close inquiry almost always turn out to have some recurrent painful or distressing affection, *e. g.* severe migraine, gastralgia or insomnia. Here the craving is for relief from pain, etc., not for morphine euphoria, and such cannot correctly be regarded as morphinists. It happens, therefore, that practically all morphinists coming under treatment have already acquired distinct tolerance of the drug; and the combating of the abstinence phenomena during withdrawal is a much more formidable problem than in the case of chronic alcoholists.

Formerly it was the practice simply to withdraw the drug suddenly, and this is occasionally done even now. But it is not a possible method except in an asylum or under conditions which give the physician complete control of his patient. Nor can I regard it as justifiable in any circumstances. Except in the mildest cases, it is horribly cruel and by no means free from the danger of causing insanity (usually temporary, however), or fatal collapse (often preceded by choleraic symptoms).

Sudden Withdrawal.—Recently, however, morphine has been *suddenly* withdrawn even in severe cases by what is known as the *hyoscine method*—a method mainly elaborated by Lott in America and introduced into this country by Purves Stewart.

A quiet, well-ventilated room, preferably on the ground floor, is selected, and the patient, after a hot bath, put to bed. Special attendants are instructed to watch him constantly night and day. The medicinal treatment commences at such time as he is well under the influence of his usual quantity of morphine. Hyoscine hydrobromide $\frac{1}{100}$ gr. is first given hypodermically. This is followed by $\frac{1}{200}$ gr. every succeeding hour until hyoscine intoxication or delirium is produced. Then the $\frac{1}{200}$ gr. injections are reduced in number, being continued just often enough to maintain the delirium for twenty-four, thirty-six or forty-eight hours, in accordance with the severity of the morphinism. One or two $\frac{1}{4}$ gr. injections of morphine may be called for during the first few hours before the delirium begins, and water to drink is freely allowed. At the end of this stage, the hyoscine is stopped, whereupon the patient soon becomes rational. Then commences the second stage. Pilocarpine nitrate $\frac{1}{8}$ gr. is injected every hour or two hours until sweating begins, being continued subsequently just sufficiently often to maintain the skin moist. This ceases with the cessation of the hyoscine symptoms. The object of the pilocarpine medication is stated to be the elimination of the hyoscine. Whether this be its effect or not, it certainly relieves the patient of his parched tongue and dry skin, thus conducing materially to his comfort. During the pilocarpine stage, pains in the knees, elbows and back, sometimes cramps, arise. For these massage is recommended. For diarrhœa, 60-gr.

doses of bismuth salicylate with 6 min. of liquid extract of colo bark are given.

The hyoscine method obviates the danger of collapse from sudden withdrawal. It saves much time and some suffering, but in my small experience I have not observed that the craving for morphine is absent at the end of the first or even of the second stage. The treatment definitely transfers the management of the case from the patient to the physician—an invaluable advantage—and thus undoubtedly enables some patients to be relieved who would otherwise prove hopeless without the aid of compulsion. But I do not think it should be considered a routine measure. It is true it has been used in a long list of cases and no fatalities are officially recorded; but hyoscine is not a drug which can be lightly prescribed. Those who intend to try the method should consult the original articles of Lott[1] and Purves Stewart.[2]

Rapid Withdrawal.—Morphine may be quite rapidly withdrawn by the aid of sodium bromide in massive doses. The alimentary canal is first thoroughly washed out by cathartics, and the daily allowance of morphine halved. Sodium bromide is then given in dram doses every eight hours. The doses are increased by 10 gr. on successive days until they reach 100 or 120 gr., *i. e.* until 300 or 360 gr. is taken in the twenty-four hours.[3] At this point the bromide is stopped, and the remaining half of the morphine tapered off during the next three days. Since the sedative influence of the bromide lasts, and even increases for some time, the period of maximum irritability resulting from withdrawal of morphine is well covered and the patient lies quiet in a semi-somnolent condition. Hot bathing and diuretics are recommended subsequently to facilitate elimination of the bromide; and later still, as the bromism weakens, mild hypnotics are required.

The treatment is entirely rational. The main source of suffering during morphine withdrawal is the grossly exaggerated condition of reflex irritability, the which is markedly reduced by the bromide salt. But it must be stated that in a few cases there have persisted, even for some months, undesirable sequelæ, *e. g.* general physical and mental debility. Such are recorded on good authority. It must not be forgotten, however, that sequelæ of the kind *may* now and then follow any method of withdrawal.

Many other methods of rapid withdrawal are advocated. One, known as the "Towns-Lambert treatment" has found numerous supporters amongst American physicians. It consists in the administration in progressively increasing doses of a "specific" composed of belladonna, hyoscyamus and xanthoxylum, together with a definite course of cathartic medication. The treatment is said to be much less violent than would appear at first sight. Its details are fully described by Dr. Alexander Lambert.[4] It is worthy of note how frequently and insistently stress is laid on the importance of free catharsis: it constitutes an indispensable item in many different plans of rapid withdrawal, and its omission is stated to involve complete failure.

Gradual Withdrawal or Tapering.—This is certainly the safest method of withdrawal and the one most usually practised, at least in this country. It is essential that the patient can afford the necessary time—and the whole of his time; for attempts at withdrawal while he continues to conduct his ordinary business are invariably futile. Furthermore, he must be *free from anxiety and worry;* and *so placed as to be unable to procure morphine surreptitiously.*

Morphine tapering differs in certain important respects from alcohol tapering. In the latter it is important to avoid any sudden large reduction during the first three or four days of treatment: in the former, it is always during these days that the largest reductions can be made. Again, while in the case of alcohol it is always easy to get rid of the smaller amounts towards the end of tapering, the exact contrary is true of morphine: there is often more difficulty in withdrawing the last grain—sometimes the last half or even quarter of a grain—than in (say) the first eleven grains.

In a few cases it is possible, without causing more than discomfort, to cut down on the first day the daily allowance of morphine to one-third: in many, to one-half; and in the great majority, to two-thirds. The only exceptions to the last reduction occur in patients who have taken the drug for many years and *who have not recently added to the daily amount;* and in those few who have themselves done some preliminary tapering before coming under treatment. Both such are probably at the time taking almost the minimum required to avoid suffering. Subsequently, each day's allowance should have a definite proportional relation to the previous day's allowance. For it does not suffice in morphinism as in alcoholism simply to subtract a regular amount per diem: roughly speaking, there should be a geometrical, not an arithmetrical, progression. But it is not possible (as it may have been on the first day) continually

[1] *Texas Medical Journal,* Nov. 1901, also *Therapeutic Gazette,* Jan. 15, 1902, p. 4.

[2] *Index of Treatment,* 1908, p. 232.

[3] Neil Macleod has given as much as 2 oz. of this drug in the twenty-four hours; I have no experience of such dosage, although I have given as much as 500 grains, and that for more than one day.

[4] *Journal of the American Medical Association,* September 25, 1909, and February 18, 1911.

to halve the allowance, still less to go on reducing by two-thirds. Probably, after the initial reduction, the most that can be accomplished with tolerable comfort is a reduction to two-thirds of the previous day's allowance. But even so, many exceptions have to be made. Whenever discomfort (which is inevitable except in very prolonged tapering) tends to pass into suffering, a halt in the reductions should be called : two or even three days may be spent on the same dose : freedom from reduction acts almost like an increase, and each succeeding day is fraught with less discomfort. Occasionally, it is good policy to give the patient a single increased dose, sufficient to free him for a time (say one night) from all abstinence symptoms. After such a rest, he will probably face the succeeding reductions with fresh courage.

The object of the plan outlined is to ensure a *continually diminishing decrease as the dose becomes smaller*. This is essential, for in every case a stage is ultimately reached at which each reduction is of very real moment. Whenever time is of no importance the tapering of the last three quarters, half or quarter of a grain should be carried out very slowly indeed. The final injection should not exceed $\frac{1}{40}$ gr. At this stage in the treatment, the patient as a rule can detect a slight but very short-lived euphoria even from this amount. With tapering carried out to this extent, all but slight discomfort may be avoided, and, what is true of no other method, the physical health begins to improve *before* final withdrawal. Moreover, the use of all adjuvant drugs can then be sometimes dispensed with.

Usually, of course, such prolongation of tapering is impossible. Then it is necessary to employ other drugs towards the end. A modification of the sodium bromide method, already described, is often very successful; or a single full hypnotic injection of hyoscine may be given every night. Or, again, these two drugs may be used together, the bromide being given during the day, the hyoscine at night. An attempt may sometimes be made to keep the patient asleep during the greater part of the day as well as during the night; but this is not often successful, and it is objectionable on other grounds. There are two important points in the use of hypnotics: (1) Full doses are necessary—hypnotics which fail to give sleep, always do harm; and (2) the use of hypnotics should be put off as long as possible in the tapering course; indeed, it is best to defer them until the end of the course is clearly in view.

Although abstinence symptoms may be avoided simply by a sufficient prolongation of the tapering, yet lack of time commonly precludes this course. Resort must then be had to drugs and other therapeutic measures. Dyspepsia yields to bicarbonate of soda, with careful dieting. For nausea and vomiting, a good plan is medical washing out of the stomach with warm alkalinised water. Sweating is promptly checked by small hypodermics of atropine ($\frac{1}{100}$ gr.), which may be added to the morphine injections. Muscular restlessness is relieved by friction and hot baths, which latter are useful for most abstinence symptoms. A mild imitation of morphine euphoria sometimes follows nitroglycerine, which certainly relieves the general vaso-constriction and chilliness of the skin so frequently observed. Caution must be employed with this drug in that it is sometimes thought capable of itself setting up a habit. Strychnine should never be given until after all morphine has been finally withdrawn : it undoubtedly intensifies the abstinence symptoms.

There is a danger in giving large doses of morphine hypodermically which is not often mentioned. Most morphinists have at times accidentally made an injection into a vein : the accident is shown by the absence of the usual tumour at the site of the injection. If the injected dose is large, the ensuing symptoms which come on instantaneously are extremely severe. They resemble the result of a large inhalation of amyl nitrite : there is a violent and extensive vaso-dilation, most marked in the head and face, which latter becomes a deep crimson. The sensation is terrifying in the extreme (the patient feels on the verge of a fit), and I have a suspicion that sudden death has occurred more than once.[1] The accident can be avoided by distributing the larger injections, either by making several punctures, or by injecting through the one puncture at several different levels.

It has been advised in the treatment of hypodermic morphinism to abandon the needle and substitute morphine by the mouth or rectum. But I am inclined to think that the disadvantages of the change outweigh its advantages. It is a disadvantage to be obliged to double the dose or nearly so; and, absorption from any part of the alimentary canal being so much more variable than from the subcutaneous tissue, there arises an increased difficulty in gauging the physiological influence of each individual dose. It is, I think, preferable to continue the method initiated by the patient. Moreover, there seems some gain in continuing the number and time of injections used by the patient. This, however, is often impossible in practice. And on the average three or four injections in the twenty-four hours given at approximately equal intervals should suffice.

It has been considered a good plan to inform the patient of each reduction made in dosage,

[1] Cases of sudden unexpected and unexplained death have been recorded several times in morphinism.

and so encourage him to take an interest in his progress. This may be advisable in some cases, but it certainly is not in the majority. Indeed, most patients, if questioned on the point, express their wish to remain in ignorance of their dosage; and I have rarely told a patient the amount he was taking without regretting it: quite often an immediate increase in the severity of his abstinence symptoms has followed the information.

For injections, the all-glass syringe should always be used. Subcutaneous abscesses are an irritating complication in new cases: they are usually ascribed to a dirty needle, but they are almost unknown in the case of those who restrict themselves to the above syringe—a fact which suggests that the plunger rather than the needle was the chief source of infection.

Treatment following Complete Withdrawal of Morphine.—A few days after the final withdrawal of the drug—the exact number varying with the duration of the tapering and other circumstances—all abstinence symptoms disappear, often so suddenly that the patient can fix almost the hour of their disappearance. He then begins to experience sensations of well-being to which he has long been a stranger. It is as if a permanent cloud had suddenly been lifted. He awakes feeling *fresh*, he begins to enjoy his meals: his interest in daily events comes back, and physical exercise, previously regarded as a duty (if taken at all), begins to appeal to him as a pleasure. Unfortunately, all this does not continue without interruption. As in alcoholism, so here, there are recurring days on which the craving for drug euphoria returns; but in the case of morphinism these intermittent cravings are more severe, longer in duration, more frequent and more persistent. Until they have finally ceased, the patient is not free from the danger of relapse, though this danger is a progressively diminishing one. Obviously, then, the patient should remain under observation, supervision and treatment for a period which depends on many circumstances. Some of these circumstances may be stated in the order of their relative importance: (1) the temperament of the patient; (2) the duration of his addiction to morphine; (3) the maximum dose to which he had attained; (4) the number of his previous relapses; and (5) his domestic environment. The drug which is most useful at this stage is in my opinion strychnine, given hypodermically in full doses.

Prevention of Morphinism.—Though undoubtedly increasing, morphinism is not yet very common in this country. Quite half of the cases occur in medical men, their wives and near relatives, and in hospital nurses, dispensers and chemists. In the remainder, with few exceptions, the habit has been initiated through medical prescription. Now, the essential factor in all cases is the disastrous knowledge and remembrance of the fascinating euphoria induced by the drug. Than morphinism we could find no better illustration of the old proverb which reminds us of the folly of wisdom in certain circumstances. For it is a fact that forgetfulness of euphoria is too frequently unattainable. Vivid remembrance is prone to arise unbidden and force itself on the consciousness in every emergency fraught with stress or worry, or even under conditions involving mere slackness or boredom. Obviously, a grave responsibility devolves on the physician who prescribes such a drug; one can conceive no greater cause for remorse than to have administered to a morphinist his first enlightening dose when other and less dangerous measures would have sufficed. And yet there can be no question that the drug is still frequently ordered without adequate justification: a well-known physician has long prescribed it in the hypodermic form as a routine treatment for sciatica.

We cannot do without morphine: its power of subduing pain and of inhibiting intestinal peristalsis—these alone would render it essential. But many precautions can be taken. It should be superfluous to say that no patient should ever be taught to handle the hypodermic syringe. Morphine should never be given hypodermically when mouth administration will suffice. And, further, morphine (or indeed opiates of any kind) should never be given even by the mouth when a less treacherous drug can be substituted. For example, it should never be given for mere insomnia: it is, at any rate, but a poor hypnotic.

I see no reason why a prescription for morphine should ever be written at all: in this tablet and tabloid age the drug can always be carried and directly supplied by the physician, even by one who does not dispense: this would actually involve less time and trouble than writing a prescription. Nor does there seem to me any justification for ever mentioning the name of the drug in the sick-room or consulting-room: the necessity for silence on this subject should be impressed upon the nurse in charge of the case. Of a certainty many cases could have been prevented by this simple precaution.

From the standpoint of avoiding a euphoria likely to make an abiding impression on the patient's memory, dosage is all-important. When it becomes really necessary to give an opiate, the dose should be sufficiently large to include sleep amongst its effects. The most dangerous doses are those which just fall short of producing sleep. Many morphinists have traced the formation of their habit to opiates which, sufficient to relieve pain, have afforded them several wakeful hours of extreme happi-

ness. Indeed, not a few have confessed to me that in these circumstances they have designedly forced themselves to remain awake, in order not to miss any of the pleasurable sensations resulting from their dose. It should be the rule, therefore, to give frankly hypnotic doses, or, perhaps better, to combine with the opiate some purely hypnotic drug, *e.g.* hyoscine or veronal.

The danger of setting up a habit by opiates, especially by morphine injections, is probably more urgent in the case of alcoholists than in any other class. Hence extra precautions are demanded. In the Norwood Sanatorium (except, of course, in morphinists) morphine is used only in rare emergencies, and then never by itself. The drug usually given in combination in the one injection is apomorphine, and that for two reasons: (1) apomorphine in emetic doses is usually itself indicated, and (2) the addition of this drug in nauseating and rapidly hypnotic doses effectually conceals the more enduring euphoric influence of morphine. It is unnecessary to add that the name of the drug (morphine) is never mentioned.

I am inclined to think that the general adoption of the above and similar precautionary measures would do far more to prevent the growth of morphinism than can ever be effected by prohibitive legislation in this country.

Perhaps it is fortunate that morphinists rarely become pregnant, the habit involving in nearly all cases a temporary amenorrhœa and sterility. Yet pregnancy may occur. Then there arises a nice question as to the best course to pursue. On the one hand, withdrawal is exceedingly liable to cause abortion, in which case the child will be sacrificed: on the other, the infant is certain to be born a morphinist (congenital morphinism) with probably a high, but unknown, tolerance of the drug already established, in which case very difficult questions of treatment, especially as regards dosage, will have to be faced. A patient of mine found herself pregnant while taking 15 gr. of morphine a day. She underwent a very gradual tapering course, with the result that she gave birth at full term to an infant normal in all respects. Such is probably the best course to adopt.

Cocainism

Cocainism seems more directly destructive of both mind and body than any other drug habit. Fortunately it is rare in this country, at any rate in its pure form. But it is not uncommon for morphinists to add small doses of this drug to their morphine injections: the addition is said to "bring out the mental flavour" of the morphine.

As to whether cocaine should be suddenly withdrawn or cautiously tapered off, there is a marked diversity of opinion. For example, K. C. Drury says: "Decocainisation should be by the gradual method. . . . Any attempt to suddenly withdraw it or very largely reduce the quantity is likely to be followed by alarming symptoms, mental and physical, mania and collapse."[1] Whereas T. D. Crothers lays it down that "Abrupt withdrawal of the drug is the safest plan. . . . In the method of gradual withdrawal it has been found that small doses may result in collapse.[2] The two views are impossible of reconciliation. I can only refer to my own experience, which, however, is small.

In those cases in which the drug in small quantities is added to morphine injections, I have always at once withdrawn all the cocaine. No bad result has ever followed: the patient has simply said he missed it. In the few cases of pure cocainism treated by me, I have in all withdrawn the drug by very rapid tapering in from two to three days, no matter what the amount that was being taken. In no case was there more than discomfort: nothing remotely resembling collapse ever occurred. In one case only there followed a mild nocturnal delirium for a few days; but this may have been due to a septic condition: there were numerous abscesses in the site of old injections and an evening temperature of 101° F.

I was encouraged to adopt such rapid withdrawal by a fact disclosed in the histories of all these patients. On more than one occasion they had through inadvertence been without their accustomed cocaine for periods varying from twelve to thirty-six hours, and had confessed that no serious suffering ensued. This is in sharp contradistinction to what happens in the same circumstances with morphinists. Also, it is a fact that, unlike morphinism, cocainism not very rarely exists in an intermittent form.

The special methods of rapid withdrawal of morphine—the hyoscine and sodium bromide methods, already described—are practicable in cocainism.

But if the withdrawal of cocaine is relatively easy, the very opposite is true with regard to the prevention of relapse. Relapse into cocainism is exceedingly common, according to some, inevitable. Whether this be due to the extreme fascination of the cocaine euphoria or to the mental degeneration which so quickly sets in, or to both, it is obvious that the supervision after withdrawal must be prolonged and careful if the patient is to have any chance of permanent freedom from the drug.

Other Drug Habits

All that has been said of the treatment of hypodermic morphinism applies, with the

[1] Green's *Encyclopædia of Medicine and Surgery*, Part XV, p. 451.

[2] *The Disease of Inebriety*, 1893, p. 360.

obviously necessary modifications, to those drug habits in which the essential factor is a morphine or opium euphoria—to morphine taken by the mouth, opium eating and smoking, laudanum and chlorodyne drinking, etc. All may be tapered off under supervision according to the general principles laid down under morphinism; and, other things being equal, it may be said that the process here is comparatively easy and fraught with less discomfort. Also, any of these drug habits, if deemed sufficiently severe or in special circumstances, may be treated by rapid withdrawal under the sodium bromide or hyoscine methods.

Chloral has long been known as a habit-forming drug; tolerance is established, and there is intolerance of sudden withdrawal. Chloralism closely resembles chronic alcoholism as regards its chief abstinence phenomenon. Sudden withdrawal in a patient who has acquired high tolerance may give rise to a typical attack of delirium tremens,[1] even in total abstainers from alcohol. Moreover, as in alcoholism, the attack begins about three days after withdrawal, and in favourable cases lasts just about the same time, namely, three or four days, ending in the crisis of sleep. Hence, in the treatment of chloralism cautious tapering on the alcoholic model is the best mode of withdrawal. It is stated that chloral delirium tremens is especially dangerous on account of the fatty degeneration of the heart caused by the drug.[2]

The comparatively modern hypnotics, trional and veronal, are now known to be capable of starting drug habits. Both drugs establish tolerance, which involves intolerance of sudden withdrawal. The most marked signs of tolerance are a peculiar anæmia and muscular inco-ordination shown by an ataxic gait. In the case of the veronal habit, at any rate, the chief abstinence phenomenon is the same as in chronic alcoholism and chloralism, namely, an attack of delirium tremens, commencing at the same interval following withdrawal, indistinguishable in its symptomatology, and lasting approximately the same time.[3] Hence the necessity of cautious tapering. F. H.

FOOD POISONING

Food poisoning may arise from most articles of diet. There exist several methods by which poisoning may occur, and a certain knowledge of these is necessary for undertaking the treatment. Thus considering meat poisoning as a type there may be the following causes—

1. **The Animal may have been Diseased during Life.**—The bacteria causing this may continue to live in the flesh subsequent to slaughtering. Such bacteria commonly belong to the "typhoid-coli" group and fall into two main sub-groups represented by (1) B. enteritidis of Gærtner and (2) B. suipestifer. The B. suipestifer is identical with the organism occurring in hog-cholera or swine-fever. Bainbridge has shown by absorption experiments that food poisoning formerly ascribed to B. paratyphosus (Type B) is probably due to B. suipestifer. These organisms can sometimes, with due precautions, be grown from the meat and also from the stools of the infected persons, these individuals, therefore, being infectious to others. It is possible that in some cases due to such bacterial disease of animals the bacteria are not present in the meat consumed, but only the toxins produced by them.

Articles affected in this manner may show no change of colour, smell, or condition, and the presence of the organisms can only be proved by bacteriological investigation. Even thorough cooking is usually insufficient to render such meat safe. The great majority of all epidemics of food poisoning fall into this class and the percentage of satisfactorily proved cases increases with the employment of modern bacteriological methods.

2. **The Meat may become Diseased or Putrefied subsequent to Slaughtering.**—Certain bacteria may infect it, especially B. proteus and B. coli. Meat infected by B. proteus may have an unpleasant smell. Thorough cooking, but not smoking, usually renders it no longer poisonous. When the organism is B. coli there are no signs. It is possible that B. proteus and B. coli are signs of contamination rather than themselves the cause of poisoning.

These two groups comprise the majority of outbreaks of food poisoning, including those due to canned foods. Formerly great stress was laid on "ptomaines." These are alkaloids of animal origin, and are of simple chemical structure. It is now believed that they are of little importance. A few poisonous fungi may act by virtue of alkaloids, but even in their case such action is doubtful.

Canned foods were formerly considered to be dangerous, owing to the risk of metallic poisoning, but the results are more often due to bacterial infections. Various parasites, such as trichinella spiralis or certain tape-worms, may be present in food and lead to infection. The treatment of these conditions is dealt with elsewhere.

The diagnosis of food poisoning usually depends on a number of persons, who have taken food from a common origin, being attacked by similar symptoms. In some cases it can be traced when a single individual has had an unusual article, such as mussels. It must be

[1] *On Alcoholism*, Francis Hare, 1912, p. 121.
[2] Cushny, *Textbook of Pharmacology*, Fourth edition, p. 192.
[3] *On Alcoholism*, Francis Hare, 1912, p. 122.

remembered that idiosyncrasy to various substances is very common, and many people are upset by a mushroom harmless to others. Cases where the disturbance can be ascribed to idiosyncrasy are rarely severe.

The treatment is considered under the following groups—

1. **Meat Poisoning.**—Beef, veal and pork are most often to blame. Mutton rarely causes poisoning.

The symptoms in an outbreak will appear in different cases after varying intervals, commonly in four to six hours, and once commenced, tend to progress rapidly. The onset occurs with nausea, vomiting, abdominal pain and diarrhœa with yellow motions.

When a case with a rapid onset is seen early the first step is to ensure that the stomach is emptied. A tube should be passed [1] and the stomach well washed out. As these poisons do not corrode the mucous membrane, this can be done without risk. In the absence of a tube, an emetic should be given.

In cases of food poisoning it is unnecessary to oil the tube.

When an emetic has been given it is important that vomiting should occur. If it does not follow shortly repeat the emetic or give one of the others. There is no reason against giving two or three consecutively. Do not wait more than half an hour.

These measures to empty the stomach should be employed even in the presence of vomiting.

The next step is to administer a brisk cathartic, the best being castor oil, giving 2 oz. to an adult. This ensures rapid passage through the intestines.

Even in early stages the pulse is commonly weak, and collapse marked, and stimulants should always be administered. Brandy is especially useful and should be given in full doses, for an adult 2 oz. should be given at once and repeated at intervals of a few hours. (It may be noted that in many cases of food poisoning those persons who have drunk wine have escaped lightly.) Strychnine $\frac{1}{30}$ gr. may be injected hypodermically. The patient must be kept in bed absolutely, and wrapped in warm blankets with hot-water bottles if there is any tendency to collapse.

The comfort of the patient may be helped by giving ice to suck and applying hot fomentations to the epigastrium and abdomen.

The diet at this stage need not be considered, as the patient can safely be starved for twenty-four hours. In any case solids should not be given.

Water should be given at all times when asked for, but a limit of 4 oz. for an adult should be placed on the amount taken at one time if the patient shows a tendency to gulp down large quantities.

If severe vomiting persists, and is causing exhaustion, the stomach should again be washed out.

In many cases the symptoms last but a few hours. The patient should not be allowed to get up for several days until all signs of weakness of the pulse and abdominal disturbance have disappeared. The diarrhœa is at first of service in ridding the body of the poisons, but as the condition advances it may become frequent and ineffectual, and attempts must be made to check it. Pulv. Cretæ Aromaticus cum Opio in doses of 40 gr. may be employed. (Tablets should never be given whole, but must be crushed to powder.) If vomiting prevents the administration of drugs by the mouth, or if the diarrhœa continues, a starch and opium enema should be given. For this two teaspoonfuls of starch are added to 5 oz. of water and the mixture heated just to boiling with constant stirring. The heating is continued for ten minutes and then the mixture is cooled and $\frac{1}{2}$ dr. of tincture of opium added. The enema is given cold through a gum elastic catheter (No. 12) with a glass funnel, and a pad of wool or lint should be pressed against the anus to aid retention of the enema.

In some cases purging arises very rapidly and severely. Castor oil must be omitted and opium given. If the vomiting and purging is extreme, morphia should be injected hypodermically.

If the symptoms have continued for a day or two, the conditions which particularly call for treatment besides the above are the diminution of the fluids of the body and the general collapse. If the skin becomes inelastic, a long rectal tube should be passed and tepid (not hot) water allowed to run in by syphon action from a height of 12–18 inches. For this the patient is turned on the left side with the buttocks slightly raised by placing a pillow below. A pint at a time should be run in if possible.

As stimulants, strychnine $\frac{1}{30}$ gr. every four hours should be injected hypodermically for twenty-four hours, and brandy given by the mouth.

The diet should be confined to milk until convalescence has set in.

Such is the treatment in cases with an acute onset and a short duration. Convalescence is usually slow.

In other instances, even with an identical origin, the onset may be slower and less acute, and the illness more prolonged, or after an acute onset the more severe symptoms may subside, and yet convalescence does not set in. Now, it has been mentioned that the organisms

[1] The preparation of emetics, and the method of passing the stomach tube, is described in the article on *Metallic Poisoning*.

commonly present in meat of diseased animals are B. enteritidis of Gærtner and B. suipestifer. Both these belong to the typhoid-coli group and may produce an illness closely resembling typhoid fever. Infection with Gærtner's Bacillus commonly results in the rapid onset of an acute attack resembling that described above. The conditions produced by B. suipestifer may be distinguishable from typhoid fever only by the agglutinating power of the serum of the patients to the various organisms and by absorption tests. Hence the illness may follow a typhoidal course either from the onset or subsequent to the acute symptoms when infection has occurred with the two types of organisms simultaneously. Such cases must be treated in the same manner as typhoid fever. It is important to note that the organisms may be excreted in the motions, which must, therefore, be treated with the same care as in typhoid fever. It is wise to take such precautions from the onset.

2. **Poisoning by Fish, Mussels, etc.** (a) *Fish Poisoning.*—The flesh of certain fish is poisonous. These are generally known and avoided. Fish poisoning is sometimes due to the fish having been kept too long and becoming infected with bacteria, especially B. proteus and B. coli. Other organisms such as B. enteritidis sporogenes may also occur. Some outbreaks have been due to organisms of the typhoid-coli group. The course and treatment of such conditions is similar to that given under Meat Poisoning.

(b) *Mussel Poisoning.*—The danger in eating mussels is considerable. The cause is yet uncertain but is connected with sewage contamination. Various organisms, including B. coli, streptococci and B. enteritidis sporogenes, have been isolated from mussels, but the clinical symptoms usually present suggest that these are not the direct cause of the poisonous effects. The symptoms usually appear with extreme rapidity, often within ten minutes of the meal, and the patient may be completely collapsed in half an hour. There is dizziness, dyspnœa and collapse, and the pulse becomes soft and very rapid. Either at this time or later intolerable itching and various cutaneous phenomena, such as urticaria, develop.

The patient must be put to bed and wrapped in warm blankets with hot-water bottles. Pass the stomach tube and wash the stomach repeatedly with large quantities of fluid. When the washings are clear, leave castor oil (1 oz.) in the stomach. In the absence of a stomach tube give emetics. Give stimulants freely: brandy in 2 oz. doses, or spirits of ether 1 dr. by the mouth, or ether 30 min. hypodermically. Inject atropine sulphate $\frac{1}{50}$ gr. hypodermically.

Recovery from the acute symptoms usually occurs within twenty-four hours, but some weakness remains for a few days.

In some cases gastro-enteritis may follow or be present from the commencement. The treatment described under meat poisoning should be followed. There is evidence that outbreaks of typhoid fever have been due to mussels, even when typhoid bacilli have not been isolated.

(c) *Poisoning through Oysters, Crabs and Lobsters.*—Several outbreaks of typhoid fever have been traced to oysters. Apart from this, oysters spoil readily and produce gastro-enteritis. Crabs and lobsters often cause gastric disturbance. Children suffer more than adults. The symptoms are often mild, but an emetic, castor oil and brandy should be administered. If severe, the stomach should be emptied, and measures carried out as described under Meat Poisoning.

3. **Mushroom Poisoning.**—There is a marked idiosyncrasy to mushrooms, many individuals being unable to consume safely even the "edible" varieties. Children especially are often affected. Poisoning, however, usually results from the ingestion by mistake of non-edible varieties. The cause of the poisoning is not yet understood. From some non-edible mushrooms the alkaloid muscarine has been isolated. The symptoms cannot be entirely ascribed to this.

In many cases mushroom poisoning has the ordinary symptoms of a gastro-enteritis, and for these the treatment described under Meat Poisoning should be followed. The washing of the stomach must be done repeatedly, as pieces of fungi often adhere to the wall.

In other cases the symptoms suggest a nervous origin. Excitement or delirium, resembling that of alcohol, occur together with disturbance of vision and pulse, and at times purging and diarrhœa. Such symptoms may be due to muscarine or other alkaloids. Except in the presence of delirium, a hypodermic injection of atropine $\frac{1}{50}$ gr. should be given. Otherwise the treatment should be the same as for the diarrhœal form.

4. **Poisoning through Canned Foods.**—Canned food may lead to poisoning owing to the action of the acids in the juices dissolving the tin or lead. This is most liable to happen in cases of fruits or vegetables. It is a rare form. Poisoning is more often due to organisms present, and the course and symptoms resemble meat poisoning. Similar treatment should be adopted (*vide* Meat Poisoning).

5. **Ice-Cream.**—Very poor ingredients are sometimes used for ice-creams sold in streets, and poisoning may result from a variety of causes. Vanilla ice-cream has caused several outbreaks. The symptoms are commonly those of gastro-enteritis and should be treated on the lines given for meat poisoning.

6. **Cheese.**—Poisoning by cheese was formerly

ascribed to an alkaloid tyro-toxicon, but probably is usually bacterial. Symptoms: Gastro-enteritis. Treatment: As for meat poisoning.

7. **Milk.**—Milk may become infected in various ways. Certain organisms present in an animal may pass into its milk. Dairymen and others handling the milk may infect it with diseases from which they are suffering or of which they are carriers. Tuberculosis, typhoid, diphtheria and other conditions may be spread thus. Apart from this, milk is usually given every opportunity of becoming a suspension of bacteria, some of which are responsible for much of the "summer diarrhœa."

8. **Specific "Sausage Poisoning"** (*Botulism*).—Almost confined to Würtemberg. Due to an anærobic bacillus (B. botulinus). Symptoms: Paralysis of cranial motor nerves. Treatment: Wash out stomach. Emetics. Stimulants. An antitoxic serum has been prepared in Germany and should be tried. H. L. T.

AUTO-INTOXICATION AND INTESTINAL INTOXICATION

We have travelled far since the days when Bouchard thought that he could detect the existence of an auto-intoxication by the simple device of comparing the toxicity of a suspected urine with that of a normal individual. For we now realise that to inject into an animal's circulation fluids differing widely in osmotic pressure from its blood gives most erroneous results. At the present time the application of the term **"auto-intoxication"** has become much restricted; intestinal intoxication resulting from bacterial changes should certainly not be so described. Strictly speaking, the term is only applicable to conditions where a metabolic defect results in the setting free of a substance which produces toxic symptoms. The clearest examples of these are to be found among the "inborn errors of metabolism," as they are called by Garrod. Apparently they are due to the absence of some specific ferment, so that some substance which would otherwise have been completely resolved into urea, carbon dioxide, water and the like passes into the circulation and ultimately has to find its way out in the urine. *Cystinuria* is a good example. Here the sulphur-containing amino acids formed from the breakdown of the proteins of the tissues give rise to hexagonal crystals in the urine, which may, if infection of the urinary tract occurs, give rise to a calculus. But even here it will be noted than an extraneous infection is necessary before the patient suffers any real inconvenience (see article on *Renal Calculi*). *Alkaptonuria* is another example. Here the tyrosin of the protein molecule gives rise to a substance which reduces Fehling's solution and also turns the urine brown on standing. The chief inconvenience from this is that the patient is likely to be rejected for life insurance, although the reducing substance is not sugar and is harmless. But there may also be some ochronosis or pigmentation of the sclerotics and cartilages and a peculiar form of chronic arthritis producing a characteristic "goose gait." Unfortunately we have at present no way of producing a proper breakdown of the tyrosin which is responsible for this curious condition. *Pentosuria* is another inborn error of metabolism in which the urine contains a sugar derived from the carbohydrate fraction in the nuclei of the cells. The condition is a harmless one, and is very rare. Again, the principal inconvenience it entails is the liability to rejection for life insurance. Failure in the breakdown of the purin groups in nucleo-proteins is usually not congenital, though the tendency to it may be hereditary. How far *gout* is to be regarded as an auto-intoxication due to this is discussed in the article on that subject. The best example of an acquired auto-intoxication due to altered breakdown in the protein molecule is *uræmia*, for the treatment of which the reader is referred to the appropriate article. This exhausts the list of auto-intoxications which can definitely be referred to the simple or compound proteins.

Auto-intoxications resulting directly from carbohydrate metabolism are very few. *Lactic acid* is formed whenever the oxidation of carbohydrates is incomplete. The principal symptom produced is dyspnœa, and it may be presumed that this dyspnœa follows on the stimulation of the medullary centres by the acid. The normal stimulant to the respiratory centre is CO_2, and if it is not present in sufficient quantities apnœa results. This soon causes some degree of oxygen starvation with consequent formation of lactic acid. The dyspnœa which results must therefore be regarded in part as a compensating mechanism for the absence of the normal stimulant. Unlike other incomplete oxidation products, lactic acid can be got rid of by inhalations of oxygen. The chief symptom it produces is muscular fatigue, affecting the striped muscle, causing cramps therein, and the cardiac muscle causing dilatation of the right heart. It may be noted that a mixture of oxygen with 4 per cent. of CO_2 will be more effective than pure oxygen, because it will continue to provide the stimulant to normal respiratory effort. Only a tentative beginning has been made with such a mixture in the treatment of Cheyne-Stokes respiration; but, as pointed out by Cushny, it is probable that such a mixture would also be useful in opium poisoning.

Oxaluria may result either from ingestion of oxalates in the food, or from fermentative

changes in the carbohydrates in gastritis or chronic pancreatitis. It is perhaps, therefore, not strictly an auto-intoxication, since the changes are presumably due to microbes. The symptoms it may give rise to and their treatment are described under *Renal Calculi*.

Of all the abnormal acids the most striking one is diacetic acid, because of its easy detection by ferric chloride or by nitro-prusside of soda and ammonia. To the former reagent it yields a claret colour, and to the latter the tint of a solution of permanganate of potash. Although it is chiefly met with in diabetes it is only indirectly due to the failure of carbohydrate metabolism, owing to the consequent incomplete oxidation of the fats and the amino-fatty acids of the protein molecule. It is a decomposition product of a fatty acid, oxybutyric acid, and in its turn may decompose into acetone. It is seldom produced in sufficient amount to cause symptoms in any other condition than diabetes. The term *acidosis* implies its existence, and *acid intoxication* its occurrence in sufficient amount to produce a toxic effect. It is also met with (*a*) under all conditions of starvation such as rectal "feeding," new growth of the œsophagus and the like; (*b*) incomplete oxygenation such as occurs in broncho-pneumonia and mountain sickness; (*c*) certain toxic conditions of the liver, such as cyclical vomiting of children (which generally seems to be the result of a B. coli infection), pernicious vomiting of pregnancy, phosphorus poisoning, and post-anæsthetic poisoning. For the detailed treatment of these conditions, reference must be made to the appropriate articles. Here it is sufficient to say that, as in diabetes, the most important part of the treatment is to prevent further formation of these acids by getting sugar assimilated by the tissues and to neutralise such acids as have been formed by the free administration of alkalis. To these ends, if food cannot be retained by the stomach, 5 per cent. of dextrose in normal saline must be given *per rectum*, while mixed alkalis must be given in the doses and by the methods described under *Diabetic Coma*. It will, of course, be understood that in diabetes levulose must be substituted for dextrose in the rectal salines. In the cyclical vomiting of children the first sign of an attack, such as a furred tongue, offensive breath, and white stools call for small doses of grey powder or calomel. Food had better be restricted to barley-water and arrowroot.

Intoxications resulting from deficiencies, either in the diet or in the defensive activity of the ductless glands, are perhaps scarcely to be included in the auto-intoxications; but it may be well to point out here that scurvy, beri-beri, and perhaps some other forms of polyneuritis may be set up by the absence of basic substances from the diet to which the name of vitamines has been given (see article on *The Dietetic Factor in Treatment*).

It is inevitable that in a work on treatment, an article on auto-intoxications must largely take the form of cross-references to articles on diseases of those organs in which the intoxication arises or produces its effects.

Intestinal intoxication is diagnosed with great frequency to account for otherwise inexplicable conditions. It is important, however, that we should have definite grounds before coming to such a conclusion. Normal inhabitants of the bowel, by straying beyond their proper limits, may produce definite infections; thus, the B. coli may set up cystitis, pyelitis, cholecystitis, or phlebitis; and the streptococcus fæcalis can ingraft itself on to heart-valves damaged by rheumatism. Or the body may fail to neutralise the soluble poisons produced by bacteria, and an intoxication may result. There are three main lines of defence against a microbe and its toxins; the resistance of the intestinal epithelium, the bactericidal properties of the blood and the antitoxic functions of the liver and ductless glands.

The infant starts with a sterile alimentary canal, but speedily acquires bacteria therein, chiefly organisms derived from the skin of the mother's nipple. In the intestine of bottle-fed children there are many more organisms of the B. coli class. As childhood goes on, the flora of the intestine becomes large and varied. Proteins putrefy, carbohydrates ferment, and to some extent these two processes are antagonistic. Putrefaction is the disadvantage of a large intestine, the advantage being the absorption of water by which the bulk of the fæces is greatly reduced, so that the bowel need not be emptied normally more than once a day. There is also less need for drinking fluid. Some extremists appear to think that it is better to dispense with the colon altogether than to possess an indolent one. But we can hardly suppose that the colon would have been evolved without a compensating protective mechanism. Putrefaction mainly affects the aromatic and sulphur-containing groups in the protein molecule. The sulphates set free are conjugated in the liver with the aromatic products to form ethereal sulphates which are practically harmless. The best known of these is indican. This illustrates the way in which the body reacts against intoxication, but it must be pointed out that there may be a large formation of ethereal sulphates with merely a trace of indican, while there is some evidence that indican may be formed within the body apart from these putrefactive changes. Merely examining the urine for indican is, therefore, not a

satisfactory method of diagnosing intestinal intoxication. We may have here also an explanation of the comparative failure of the phenol compounds as intestinal antiseptics. By combining with the sulphates they deprive the body of the power of rendering harmless those putrefactive substances the formation of which they cannot altogether prevent. It helps us further to understand the value of sulphates in certain intestinal diseases. They are not only aperient but antitoxic.

The following types of intestinal intoxication have been recognised—

1. *Indolic* due to the B. coli and perhaps the B. putrificus. The commonest form is seen in marasmic children with a distended abdomen and chronic intestinal indigestion. The subjects are sharp-witted, intolerant of cold and easily fatigued. Carbohydrates are not well digested. There is a marked increase in the indican and other ethereal sulphates in the urine. As for treatment, the carbohydrate should be restricted to well-cooked rice and biscuits. Milk should be peptonised for a time, and a moderate amount of finely divided meat given. Gelatin may be useful because it contains no tryptophan, the precursor of indol. A few rather generous meals are better than frequent feeding. High irrigation of the bowel may be beneficial.

2. *Butyric* chiefly due to B. ærogenes capsulatus. The bacterial action sets free nascent hydrogen, which causes much reduction of the bile pigment, so that there is an excess of urobilin in the fæces and urine. Addition of a strong solution of mercuric chloride to the fæces produces a red colour, rendered more distinct by subsequently throwing them into water. There is little or no indican in the urine. Indefinite invalidism may be the chief symptom. The patient is often sour-smelling, the epithelium of the tongue and mouth is seen to be desquamating. Hence the irritable condition of the alimentary canal with the tendency to diarrhœa. Anæmia supervenes owing to the hæmolytic action of the toxins found in the bowel. The treatment should be on the general lines described below.

3. *Combined Indolic and Butyric.*—In this, nervous symptoms occur early. The outstanding features of the case are mental depression and muscular fatigue. The subjects become invalided more rapidly than with either of the former types occurring separately.

4. *Carbohydrate Fever.*—It is not clear how far this type coincides with the fermentative type described under (2). It is certain, however, that rigid restriction of the carbohydrates in the diet leads to marked improvement, while carbohydrate excess may cause an exacerbation of symptoms.

5. *Sulphæmoglobinæmia.*—A curious form of cyanosis has been found to be due to the presence of sulphæmoglobin in the red corpuscles of the blood. Lately Mackenzie Wallis has found a nitrifying bacillus in the saliva in these cases. The nitrites reduce oxyhæmoglobin after absorption from the intestines, and sulphuretted hydrogen can then readily form sulphæmoglobin. Great benefit has been derived from the removal of all infected teeth, administration of an autogenous vaccine prepared from the organism in the saliva, and the free use of saline aperients.

6. *Methæmoglobinæmia* is less common, and, no doubt, several of the cases so described have really been ones of sulphæmoglobinæmia. In this condition there is also cyanosis, but the spectroscopic appearances of the blood are different. It may also be brought about by the habitual use of coal-tar drugs. Avoidance of all such drugs, a rigid milk diet and insoluble intestinal antiseptics are the main points in treatment. There is usually diarrhœa, which may also have to be treated.

7. *Pressor Diamines* have been discovered in the bowel by Barger, Walpole and Dale. They are, no doubt, responsible for the rise of pressure which frequently occurs in later life without obvious cause, especially in constipated persons. The treatment is that described under the prophylactic measures in chronic interstitial nephritis (*q. v.*) in addition to the ordinary methods.

The general scheme of treatment suitable in cases of proved or suspected intestinal intoxication is as follows—

1. *Avoidance of Putrefactive Contamination of Food.*—All food should be cooked as far as possible. Cheese, especially the riper varieties, should be avoided, as should high game. All fruit should be peeled. Careful attention must be paid to the teeth, since anærobic bacteria which lurk in the interstices are a great factor in intestinal putrefaction.

2. *Promotion of Prompt Digestion and Absorption.*—Here again attention to the teeth is important to allow of proper mastication. Hydrochloric acid should be given if it is deficient in the gastric juice. But in the cases of butyric fermentation diastatic ferments such as Taka-diastase are better than hydrochloric acid, which is not well borne. Pepper, mustard, excess of salt, vinegar and lemon are irritant to these patients. Demulcent drinks are indicated. The butyric type need careful preparation for a generous diet. Emotional irritability or mental depression, increase in the ethereal sulphates of the urine, of gas-producing bacilli in the stools, or of intestinal flatulence are signs that the food should be reduced. Intestinal flatulence indicates reduction

in the amount of carbohydrates. If there be atonic dilatation of the stomach, lavage should be employed. Rest after meals should be enjoined.

3. *Limitation of the Number of Bacteria.*—Though it is obviously impossible to render the intestines sterile, the number of bacteria can certainly be considerably reduced. Calomel in small and divided doses followed by a saline purge next morning is a time-honoured method of attempting to effect this. However useful this may be to start treatment, we must beware of a routine use of strong purgatives, for, by removing the superficial epithelium of the bowel, they may facilitate septic absorption. After a preliminary dose of calomel, my custom is to give 3 min. of Cyllin Medical in capsules three times a day for not more than four days. If continued longer than this, I think it is apt to cause irritative symptoms. After that naphthalene tetrachloride in 5 or 10 gr. doses should be given three or four times a day. As it is insoluble and cannot, therefore, be absorbed, it does not produce any toxic symptoms. Salol has not been a success, but cachets of β-naphthol in 5 gr. doses sometimes give good results. A cachet containing 3 gr. of benzo-naphthol and $\frac{1}{4}$ gr. of menthol is useful where there is much flatulence. Izal in 2 min. capsules has been particularly successful in some cases of paratyphoid infections. Thymol, manganese dioxide, hydrogen peroxide and ichthyol have all been recommended by different observers.

Instead of attempting to render the bowel aseptic, Metchnikoff advised the introduction of lactic-acid-producing organisms which are antagonistic to the growth of putrefactive bacteria. Soured milk has long been a staple article of diet among oriental people; it enjoys a high repute as a hygienic measure and is claimed to promote longevity. This lactic-acid treatment has been ridiculously boomed. In many cases no living bacilli or the wrong organisms were taken. In others the cases were totally unsuitable. The treatment is contra-indicated in hyperchlorhydria and rheumatism, and in cases where the intestinal disturbance is due to abnormal fermentation of the carbohydrates. Tablets of all kinds are unsatisfactory as a method of administration of such delicate organisms, and only fluid cultures or milk actually soured by, and containing the bacilli, should be used. This is better than simply giving lactic acid, which is almost certainly absorbed before the point where it is required is reached. Apart from cases where benefit is derived from this treatment, simply by suggestion, or because it enables a patient to take a considerable quantity of a nourishing and usually easily digested food, a specific action can only be expected where the microbe responsible cannot flourish in an acid medium. The reaction of the fæces will be a guide: if they are acid, this treatment is unsuitable, if they are alkaline at first but yield a fair quantity of gas in the fermentation tube, and then show an acid reaction, the treatment will probably not be successful. Good results can only be expected when the fresh fæces are alkaline, and remain alkaline after twenty-four hours yielding hardly any gas to the fermentation tube.

4 *Guelpa's distoxication method* may be given a trial in robust subjects, in view of the excellent results claimed for it by various observers. The method is as follows. For three or four days and sometimes longer, a bottle of purgative water is taken. Guelpa recommends that the following mixture should be dissolved in half a litre of boiling water—

Magnesium citrate ℥ x
Calcined magnesia gr. xxx
Sodium chloride gr. xv
Essence of citron ♏ x

This is to be taken in the morning quite hot, in two doses at ten minutes' interval. During these days no food of any sort is taken, but a mineral water, such as Evian, is drunk freely; or a tisane, such as tilleul, sweetened with a little saccharin. As after all fasting procedures, ordinary diet should only be cautiously resumed.

5. Plombières douches are much advocated by some authorities. The douches should never be given more than three times a day, and never under a pressure of more than 18 inches. Nor should they be continued more than for three weeks at a time, otherwise they are certain to produce colitis.

6. *Vaccine Treatment.*—This has yielded good results in several cases. Elaborate means may have to be taken to identify the responsible microbe. A plate culture is made from the stools and the effect of the patient's blood in agglutinating or destroying the more definitely pathogenic organisms tried. A positive reaction would justify the use of a vaccine prepared from such organisms.

7. *Mechanical Supports.*—Where there is definite visceroptosis much help may be derived by a well-fitting abdominal support, and of these, in my opinion, Curtis's is by far the best.

8. *Surgical Procedures.*—Irrigation of the colon through an appendicostomy wound, short circuiting, and even excision of the colon have all been advised but should only be considered where all medical means have been exhausted without improvement.

W. L. B.

TREATMENT OF DISEASES OF METABOLISM

DIABETES MELLITUS

Corresponding to the age of the patient and the degree of the glycosuria, very different results may be expected in the treatment of diabetes. Generally speaking, the younger the patient, the less amenable will he be. The treatment of ordinary cases is still mainly negative, the aim being to diminish the glycosuria and to prevent the occurrence of acid intoxication, for only exceptionally can we go deeper and attack the origin of the metabolic defect in some definite disease of a ductless gland. With increase in our knowledge of the internal secretions we may look forward to being able to do this more frequently. Naturally, a careful search should be made for evidence of disease of the pancreas, thyreoid or hypophysis, and, if found, appropriate treatment should be applied.

The first step in the treatment of diabetes was Rollo's discovery that limitation of the carbohydrate intake was followed by diminution of the glycosuria and by relief of symptoms. For many years the whole aim was to discover an absolutely carbohydrate-free diet and to restrict the patient rigidly to this. This conception was based on inadequate knowledge and ignored the following facts—

1. Proteins contain fractions which can yield sugar, and excessive protein diet is so stimulating in its metabolic effect that it causes further breakdown of the tissues, with consequent setting free of more carbohydrate molecules.

2. The failure of a diabetic to metabolise carbohydrates is seldom absolute, and careful search will generally reveal some form in which they can be tolerated to at any rate a limited extent.

3. Assimilation of some carbohydrate is essential to metabolism; in its entire absence the body has to draw on fats which it is unable to oxidise completely without their aid. This results in the formation of abnormal fatty acids. To eliminate these the body has to provide ammonia from its protein and calcium from the tissues generally, thus increasing the wasting.

It will be seen that an absolutely carbohydrate-free diet or a total failure to utilise carbohydrate must result in a metabolic disaster in which protein, fats and mineral salts alike share. Coma is the clinical expression of such disaster. The craving of the individual for a mixed diet is the unconscious expression of a fundamental physiological fact.

At best, this search for a carbohydrate-free diet was the outcome of a negative ideal and had but a limited aim. The newer conception offers far greater possibilities of permutations and combinations in the diet to suit the metabolic defect in each individual case. Incidentally, it thrusts the drug treatment of diabetes more than ever into the background.

We may summarise the indications for treatment in diabetes thus—

1. Control of the hyperglycæmia, which involves loss of energy and is the cause of many complications.
2. Increase in the patient's tolerance of carbohydrates.
3. Prevention or control of acidosis.
4. Treatment of complications.

These indications are not independent of each other; thus, increasing sugar tolerance automatically diminishes both hyperglycæmia and acidosis.

Before beginning treatment the amount of sugar in a twenty-four-hour specimen of the urine is estimated on an ordinary diet. Diacetic acid is also tested for by ferric chloride. If this reagent imparts a claret colour to the urine while the patient is still on an ordinary diet, the case is a severe one, and special caution must be exercised in establishing restrictions. A sudden restriction of the diet is unjustifiable and involves grave risk of coma. This risk is, moreover, increased by confining the patient to bed during the process of restriction. At first no starch, but all the sugar except that contained in a pint of milk, is removed from the diet. A mixture of alkalies is prescribed as explained under *Acidosis*. The urine is tested daily for sugar and diacetic acid; so long as the former falls without the appearance of the latter, restrictions may be steadily increased. Thus only a small amount of milk should be allowed in tea or coffee, and bread should be reduced to 2 oz. at two meals a day. The idea that toast is less injurious than bread is fallacious; the only advantage of it is that as it requires more mastication less of it is usually eaten. But being drier it contains a higher percentage of carbohydrate. If the diacetic reaction appears at any stage the diet should not be further restricted for a time, but it need not be relaxed at once unless the reaction becomes distinctly more marked, for diacetic acid makes a temporary appearance in any one on a restricted diet. If the case is going on well, sugar will gradually disappear from the urine at some stage in this process.

The part played by alcoholic excess in

producing glycosuria, usually of an amenable sort, must be remembered. Champagne is particularly apt to excite it in some people. Yet, as shown later, moderate amounts of alcohol may help in severe diabetes.

It is important to determine as accurately as possible the degree of tolerance of carbohydrate in each case. For this purpose some standard diet of known carbohydrate content is necessary. The following is the one suggested by Von Noorden—

Breakfast.—Coffee or tea with one or two tablespoonfuls of thick cream, 6 oz.; hot or cold meat (weighed after cooking), 3 oz.; butter; two eggs with bacon; white bread, 2 oz.

Lunch.—Two eggs (cooked as desired, but without flour); meat, about 6 oz.; vegetables, such as spinach, cabbage, cauliflower, asparagus, prepared with broth, butter or other fat, eggs or cream, but without flour; cheese and butter, 1 oz.; two glasses of light wine; one cup of coffee, with one or two tablespoonfuls of thick cream; white bread, 2 oz.

Dinner.—Clear meat soup (with eggs or vegetables); one or two meat dishes with vegetables, salad of lettuce or tomatoes; wine; no bread.

Drinks.—One or two bottles of ærated waters.

If this diet, which contains about 100 gm. of carbohydrate, does not cause any glycosuria, then the bread is gradually increased until sugar appears. If sugar does appear with this diet, it may be continued for a few days until the sugar is constant and the bread then diminished.

If the urine becomes free from sugar on a restricted diet without diacetic acid making more than a temporary appearance, the restrictions should be maintained for at least a month. Physiological rest allows of at any rate a partial recovery in the sugar-forming apparatus, and as long as abnormal acids do not persist no harm is done to general metabolism. Then a cautious relaxation should be attempted. The following principles must guide us in carrying this out.

Wheat flour is often badly tolerated, and the greatest difficulty is to find a satisfactory substitute for bread. Gluten bread was introduced by Bouchardat in 1841; it is prepared by washing away the starch from flour, leaving the more tenacious vegetable protein behind. It is almost impossible to wash away all the starch, and gluten bread nearly always gives a blue colour with iodine. But it is easy to remove enough starch to leave a very unpalatable residue, and, sooner or later, the patient revolts against it. I seldom use gluten bread as a routine, employing instead limited quantities of ordinary bread if it can be tolerated, or the Brusson-Jeune rolls, which contain less starch than bread and are palatable. Casoid bread or Kalari biscuits taste better than gluten bread, and are free from starch; they should be given a trial. If the patient cannot do with as much starch as is contained in Brusson-Jeune rolls, it is advisable to interpolate days on which gluten, casoid or protene bread is given. Other substitutes for bread are made from aleuronat flour, soya beans or almonds, but, like gluten bread, they are expensive and soon become distasteful. They may be acceptable for a change.

Potatoes are generally tolerated better than bread; in fact, a "potato cure" has been instituted in which they are given largely, but this is not advisable since tolerance for them is limited. On relaxing the diet it is well to add one and then two potatoes of average size (*i. e.* about 3 oz. each in weight) to the daily food, watching the effect upon the urine.

Of all the forms of carbohydrate, oatmeal is usually best tolerated and is strongly recommended by Von Noorden; 8 oz. are given in the day, either as gruel, in cases of impending coma, or as porridge or oatcake with eggs on certain days in the course of treatment. I have been favourably impressed by it, and there is a general agreement as to its value.

Fruit sugar (levulose) can often be assimilated up to 50 gm. (rather less than $1\frac{2}{3}$ oz.) in a day, cautiously given in doses of not more than 5 dr. at a time. If more is given than can be consumed by the tissues at once, it will be stored as glycogen and subsequently turned into dextrose, which will be excreted. Its cost, however, is prohibitive except for wealthy patients or in emergencies such as threatened coma. I have seen striking benefit from its use. Artichokes are rich in inulin, which breaks down into levulose. This provides a cheaper way of supplying levulose, and I have given moderate amounts of artichokes without increasing glycosuria.

Our object, then, should be to select from potatoes, oatmeal or artichokes the form of carbohydrate which can best be assimilated. If the urine cannot be freed from sugar in this way, the next step is to investigate the effects of various proteins on the glycosuria. Meat proteins may have a distinct influence in maintaining it. This, which is insisted upon by Von Noorden, is often overlooked and the patient is allowed to take meat freely. As a matter of fact, he can often take a vegetable diet, which must contain a good deal of carbohydrate, better than he can manage a carbohydrate-free diet with abundant meat. It is not so much that the carbohydrate fraction of the meat protein is not well borne as that the meat has a stimulating effect on the tissue metabolism.

Recent observations of Thompson and Wallace on the increase of glycosuria when meat extracts were given support this view, though I may add that some cases I investigated with Dr. Roper did not show intolerance to meat extracts. However, when we find that either meat or oatmeal can be tolerated separately, but not when given together, we must conclude that meat proteins diminish the tolerance of the body for carbohydrate in many cases.

Von Noorden finds that the order of tolerance is: meat proteins least, then casein, next cooked eggs, and, finally, vegetable proteins, especially in the form of glidine, best of all. The best scheme seems to be to alternate the days of carbohydrate-free diet with days of oatmeal diet and days on which little but eggs and vegetables are taken. Fast days with rest in bed may also be interpolated, as on Guelpa's plan (see p. 168). But in cases with marked acidosis this is not free from risk.

I will give one or two examples of such schemes, but as every diabetic is a law unto himself, careful investigation is necessary to find a plan which suits each case.

1. Vegetable, egg and oatmeal scheme.

In the course of an ordinary restricted diet a week of the following diets is introduced once in six or eight weeks—

(*a*) For two days a diet of lettuce, cabbage, spinach, veal broth, three eggs, butter, two lemons for lemonade and coffee. (Personally, I prefer to do without the veal broth, if possible, for reasons already given.)

(*b*) For three days a diet of 8 oz. of oatmeal as porridge or oatcake, 4 oz. of butter, five eggs, two lemons and coffee.

(*c*) Two days of (*a*) again.

2. Three weeks of restricted diet, *i. e.* no carbohydrate, with the addition of 60 gm. (approximately 2 oz.) of bread. One day of vegetable-egg diet; one fasting day—only weak tea, lemon-squash or whisky-and-soda in suitable cases are allowed, with rest in bed. One day of vegetable-egg diet; four days of carbohydrate-free diet. Then the same scheme begins anew. This plan is one recommended recently, among others, by Von Noorden at the International Medical Congress.

3. Von Noorden records another instance in which a patient kept well for years, exhibiting remarkable energy and remaining free from complications on the following scheme: The ordinary diet was limited in protein and contained 80 gm. (approximately 2½ oz.) of bread daily; every fifth day, a vegetable-egg diet was employed, and, every second month, a series of vegetable-oatmeal days.

4. Marcel Labbé advises the following diet, which may be given for two or three days at a time—300 gm. (about 9 oz.) of leguminous vegetables (peas, broad beans, haricot beans, lentils, soya beans), some green vegetables, 150 gm. (about 4½ oz.) of butter, 5 or 6 eggs, 3 to 6 aleurone heads, and a little red wine.

A marked increase of tolerance of carbohydrate often follows. I have generally used the first and last of these schemes, and have noted a distinct improvement, the urine becoming quite free from sugar in some cases—at any rate for a time. In any case I am accustomed to recommend entire abstention from meat one day in each week. It is necessary, from time to time, to see how the patient tolerates different carbohydrates. If the urine cannot be rendered free by any means, the best point at which to maintain the patient's metabolism is that to which the intake of carbohydrate can be raised without increasing glycosuria while diminishing the acetonuria.

It is clear that some of these schemes can be carried out much better in a nursing home. It is almost impossible to keep records of the intake and output in the patient's own home, and Cammidge has recently emphasised the importance of quantitative as well as qualitative regulation of the intake. After the food has been regularly weighed for some time, the patient quickly learns to judge with the eye the approximate weight of the food he is taking, and then the treatment can be continued at home after his tolerance for different forms of carbohydrate has been estimated.

Control of Acidosis.—Recognition of the significance of acidosis has profoundly modified our treatment of diabetes. It is probable that there are never more than traces of acetone in the urine though it may be present in the breath. Hurtley has recently shown that the nitroprusside test, which was thought to be a test for acetonuria, is really a more sensitive test for diacetic acid. In any case, acetone is a mere decomposition product of diacetic acid which, in its turn, is derived from the breaking down of fats that almost always occurs during starvation or even deprivation of carbohydrate.

It naturally follows that the most effective treatment of acidosis is to find a form of carbohydrate which can be assimilated. Then the fall in the amount of both diacetic acid and sugar in the urine is often striking.

Investigations have been made as to the possibility of replacing carbohydrate in metabolism. Citric and glutaric acids do so to a limited extent. Citrates can be added to the alkaline mixture, which should always be given when the diet is being restricted or when acidosis is marked. Alcohol appears to be able to replace carbohydrate rather more satisfactorily. Bearing in mind the dangers of the alcohol habit and that alcoholic excess excites glycosuria, it is nevertheless advisable

to give alcohol in acidosis to the extent of about an ounce of the pure spirit in the day. Malt liquor, sweet wines, champagnes and liqueurs must be avoided. Since diacetic acid comes from the breaking down of fats, the question arises as to the advisability of giving fat in food. To do without fat would be to deprive the patient of an important source of energy, and it is a relief to find that the administration of fats in the food does not apparently increase acidosis. The only exceptions to this are the lower, more volatile, fats. Butter, therefore, should be kneaded in water before the diabetic eats it, for in this way the more volatile fats are extracted.

The use of alkalies in acidosis is an essential part of the treatment. Spriggs has pointed out that in the normal individual 2 dr. of bicarbonate of soda will render the urine alkaline for twenty-four hours, but if an excess of acids is being formed this is not enough, so that the amount of alkali that can be taken without neutralising the urine is a rough measure of the degree of acidosis.

In some cases it is impossible to render the urine alkaline at all, and I have seen a case where, with the fullest doses of alkali (*i. e.* about 1 oz. every three hours) the acidity of the urine was still twice that of normal. A more accurate measure of acidosis is the amount of ammonia in the urine, which can quickly be estimated by the formalin method. This also has a prognostic value, for a marked rise in the ammonia suggests the risk of coma, though Naunyn's statement that if the ammonia excretion reaches 4 gm. a day nothing can prevent coma is too dogmatic. The normal output of ammonia nitrogen is about 1 gm. a day, and, in severe cases of acidosis, may easily reach 3 gm. If the condition improves under treatment, the urine will become alkaline, and the amount of alkali may gradually become diminished without the return of the acid reaction. It is not sufficient to give sodium alone, as is so often done, for other metallic bases are also being drained from the tissues, particularly calcium. Also, if one metallic salt is given out of proportion to the others, it increases the excretion of those others. I employ the following mixture, based upon the relative proportions of the metals normally present in the urine—

Sod. Bicarb. ʒ i
Pot. Citrat. gr. xxx
Calcii Lactat. gr. iii
Mag. Carb. gr. iii
Aq. ad. ℥ i.

This is given three times a day, and increased up to three-hourly doses, according to the severity of the case.

It has been urged against this method that it increases the intensity of the diacetic reaction in the urine, at any rate for a time. But this is merely because the excretion of the acetone bodies is being facilitated, not because their production is being increased. They are now excreted as metallic diacetates instead of in combination with ammonia derived from the breaking down of the proteins of the tissues. This alkaline treatment should never be omitted in severe diabetes. That it is not more successful shows that we do not yet completely understand the pathology of acidosis. The breakdown of proteins probably plays a larger part in it than is at present realised.

Drug Treatment of Diabetes.—Though alkalies are of distinct value in the treatment of acidosis, drugs have a very limited application to the treatment of glycosuria. Codeia has the greatest reputation in this respect, and apparently helps in some cases. It probably acts by depressing the general metabolism. It is apparently excreted as a glycuronate, and it must be remembered that this substance reduces Fehling's solution. Recently I saw a man who had had glycosuria for some years and who was taking codeia. He still had a small amount of reducing substance in his urine. I did not think it was sugar, and on testing with phenyl hydrazine obtained the osazone of glycuronic acid and not of dextrose, showing that the persistent reducing substance was due to the codeia he was taking. This is a serious source of fallacy which must not be overlooked. In any case, it is quite unnecessary to give codeia when there is merely a trace of sugar in the urine.

Salicylates, also, have some reputation in the treatment of glycosuria. The chief objection to their use is that they mask the ferric chloride reaction for diacetic acid in the urine. They do not mask the nitroprusside reaction, however. As it is probable that salicylates can promote synthesis of purins in the body, there is no inherent improbability that they can help in the synthesis of carbohydrate also, though we have no proof of this. On the whole, I have not been greatly impressed with the action of salicylates in glycosuria. Aspirin has been used, but Von Noorden has observed the onset of nephritis during its administration. It was not certain that the aspirin was responsible, but no other cause could be found.

Arsenic occasionally seems to help, and other drugs such as jambul may diminish glycosuria, at any rate for a time; 5 to 30 gr. of the latter can be given in cachets. Its prolonged use is apt to set up gastric irritation. I have never observed improvement which could be attributed to any other drugs.

After-Treatment.—When the urine has been

rendered free from sugar, lowered tolerance for sugar and hyperglycæmia will probably persist. Before we can pronounce a patient cured we must know that the sugar tolerance has been restored to normal limits, and that there is no excess of sugar in the blood.

In cases of intermittent glycosuria it will generally be found between the attacks that a small quantity of dextrose will produce glycosuria and that there is still an excess of sugar in the blood.

All this indicates the advisability of keeping the patient on the same line of treatment for a considerable time after the urine has become free from sugar.

In this connection, reference should be made to those cases of so-called renal diabetes in which there is no excess of sugar in the blood, but rather a diminution. These cases of hypoglycæmia do not show much response to diet and are probably of a comparatively harmless nature. Garrod, however, has reported a case in a boy whose elder sister had typical diabetes. This hardly suggests that renal glycosuria is entirely distinct from ordinary diabetes, and as a precautionary measure we should in such cases prescribe restriction of carbohydrates in the diet, but not their complete absence.

Spa Treatment.—For a more detailed account of appropriate spas in the treatment of diabetes, reference should be made to the article on *Climatology*. In general, it may be said that it is only the milder cases that are amenable to spa treatment. There is considerable risk in sending a thin diabetic, who is passing a good deal of diacetic acid, on a long journey, and I have certainly seen patients made worse in this way. Carlsbad, Marienbad and Neuenahr are not likely to be visited by English patients for many years. The milder régime carried out at the Hermitage, Evian, may suit some cases, and there are full facilities there for dietetic treatment to be carried out combined with rest in pleasant surroundings.

Treatment of Complications

1. **Diabetic Coma.**—Once coma is thoroughly established nothing more than a temporary rally can be expected, but a good deal can be done in the way of prophylaxis, as has been described in the treatment of acidosis. Carbuncles, overfatigue and constipation are potent factors in provoking coma. On the first suggestion of drowsiness, air-hunger, burning pain in the pharynx or epigastrium, or bilious attacks, the administration of alkalies should be increased and 5 dr. of levulose should be given three times a day. A very extensive relaxation of the diet is probably inadvisable, but 2 pints of milk, though it will increase the glycosuria, may help in impending coma.

If there has been persistent constipation it is a wise measure, which I have found occasionally successful, to have the rectum cleared out and 3 per cent. of bicarbonate of soda with 4 per cent. of levulose given by drop enema until about a litre of fluid has been given.

When coma has developed despite these measures the case is hopeless and a temporary rally is the most that can be hoped for. This, however, may be of great value in order to enable the patient to sign a will and to recognise his friends. About 30 oz. of normal saline, containing 2 per cent. of sodium bicarbonate, may be run slowly into the median basilic vein at about body temperature. It is well to remove from 7 to 15 oz. of blood first. A similar infusion may be given into the other arm four to six hours later. The temporary improvement is sometimes striking. Stronger solutions are sometimes recommended, such as 5 per cent. of sodium carbonate. The addition of sodium acetate, 1 per cent., has been advised, but I have no personal experience of it. Some authorities believe that normal saline is as effective as the alkaline fluid, but I have not found it so. I have added 2 per cent. of levulose to the fluid, but am not convinced that it is advantageous when the patient is actually comatose.

The treatment of other complications of diabetes resolves itself into the diminution of the glycosuria with the application of ordinary principles to the special lesion. Thus—

2. **Diabetic Neuritis**, which is apt to occur in all persistent cases to a greater or less extent, soon clears up when the sugar disappears from the urine. The condition sometimes simulates tabes. Aspirin may relieve the pains very considerably. When they can be borne, massage, ionisation and electrical baths are a great help. The complete ophthalmoplegia which sometimes occurs in diabetes is apparently due to neuritis. The prognosis is not bad. Treatment, in addition to appropriate diet, consists in giving strychnine internally, and electricity. Dr. E. P. Cumberbatch has kindly sent me the following note on this subject: "Electrical treatment may be applied to the orbital muscles when paralysed, but it is difficult to carry out because these muscles lie deeply, and currents that are sufficient to cause them to contract would cause too much pain in the conjunctiva and produce disagreeable sensations by stimulating the retina. Some improvement, however, may follow electrical treatment, and it is not essential that visible contraction of the muscles should be produced. A continuous current should be passed through the orbital cavity, one electrode being a small sponge moistened with 1 per cent. salt solution and placed on the closed lids.

This electrode should be the kathode. The anode may be placed on the neck. The current should be made to vary in strength slowly and rhythmically. The discharges of small capacity condensers may prove to be of value in the treatment of ophthalmoplegia. These discharges are of exceedingly short duration, and, if they are sufficiently brief, may not appreciably excite the sensory nerve or the retina."

Other palsies are rare, but Dr. Edmund Hobhouse has told me of a case of abductor paralysis of the vocal cords with glycosuria which cleared up when the sugar disappeared from the urine.

3. **Perforating ulcer** only occurs when neuritis already exists. Beyond treatment of the neuritis, all pressure must be taken off by complete rest, sodden epithelium removed, the ulcer washed with equal parts of warm water and 10 vol. per cent. of hydrogen peroxide two or three times a day, and then well dusted with equal parts of zinc oxide and starch powder. It may be advisable to use, as a preliminary measure, boroglyceride fomentations, thoroughly wrung out, or a bath containing a little liquor iodi or permanganate of potash.

4. **Gangrene** if truly diabetic in nature only occurs, like the perforating ulcer, when there is neuritis. But an elderly diabetic seems unusually prone to atheromatous gangrene. In the former condition the knee-jerks will have gone, the gangrene is moist, and diacetic acid is almost certain to be present in the urine; in the latter the knee-jerks may be present, the gangrene is much drier, and there need be no acidosis. The treatment will vary according to which of these two conditions are present. In the former every effort must be made to diminish the hyperglycæmia, which provides the micro-organisms with abundant pabulum. The local treatment may be carried out on the same lines as for perforating ulcer. Early amputation is indicated, as the gangrene tends to spread rapidly. The defective sensibility of the legs in neuritis necessitates caution in the use of hot-water bottles, which may produce gangrene by causing sores. If arteriosclerosis is the cause of the gangrene, vaso-dilators and diffusible stimulants should be given, and the part warmly wrapped up. Here, too, operation will probably become necessary, but there is not the same need for haste, as the gangrene does not tend to spread in the same way and a definite line of demarcation will appear. The small ulcerated patches over the internal malleoli are not really perforating ulcers or allied to gangrene. They may appear while the knee-jerks are still present. They originate in the sebaceous glands. They should be treated by cutting a piece of lint to the shape of the patch, moistening it with a stimulating lotion such as 2 gr. of zinc sulphate to an ounce of water, and renewing it every day. The lint is then covered with a piece of oiled silk, also cut to the size of the patch, and bandaged. After three days of this treatment a dusting powder of zinc oxide and starch should be used instead.

5. **Carbuncle.**—This is a serious complication in diabetes, both on its own account and because it may excite coma. If it is small a ring of collodion may be painted round it to produce hyperæmia and prevent its spread. The use of a suction cup after a small incision has been warmly recommended. The suction should always stop short of producing pain. Short repeated applications are better than a single prolonged one. Three to six applications, lasting five minutes each, with intervals of three minutes between, are advised by J. M. Graham. Ionisation may be tried with a zinc needle as the positive pole inserted into the middle of the swelling. An old-fashioned remedy is the injection of a drop of pure carbolic acid into the carbuncle. If it does not yield quickly it will probably be necessary to make a free incision into it and scrape out the slough. Dressings with sterile horse serum have been found useful. In chronic cases an appropriate vaccine should be tried. It is of the first importance to support the patient's general condition, which is liable to become profoundly asthenic.

6. **Pruritus** of the vulva is a common complication, and may be the first thing to call attention to the glycosuria. It generally subsides quickly if the glycosuria can be controlled. Of local measures the best is frequent bathing with subsequent application of a lotion composed of glycerine of tannic acid and sulphurous acid, ½ to 1 dr. of each in an ounce of distilled water. This prevents fermentative changes in the saccharine urine which sets up the pruritus. An ointment of 10 gr. of menthol in an ounce of vaseline, or a lotion of 20 min. of chloroform in an ounce of olive oil may help to allay the itching. Pruritus of the glans penis is much less common, and should be treated on similar lines.

7. **Eczema** should be treated on ordinary lines.

8. **Respiratory complications,** such as phthisis, bronchopneumonia and gangrene of the lung, must be treated in the usual way. Phthisis generally runs a rapid bronchopneumonic course. The patient must not be too strictly dieted, and the sugar may disappear spontaneously from the urine as the tuberculosis advances.

9. **Albuminuria.**—The association of albuminuria with glycosuria is common. In some of these the glycosuria is "renal" in nature, that is to say, it is accompanied by hypoglycæmia. In this case treatment should be

concentrated on the kidney condition, as the glycosuria has not much significance. In others alcoholic excess may be responsible, and if this is corrected the glycosuria soon proves amenable. In one such case I saw, even moderate restriction of the amount of alcohol caused the glycosuria to clear up, only to return with each drinking bout. On the other hand, prolonged glycosuria almost inevitably leads to albuminuria in time, probably from irritation of the kidney. As long as it does not cause raised tension, cardiac hypertrophy and other signs of cardio-vascular disease, one need not trouble very much about the albuminuria. The treatment is merely that of the glycosuria.

10. **Digestive disturbances** are fortunately rare. They may arise from excessive intake of proteins, for which the best thing is a few days of Von Noorden's vegetable, egg and oatmeal diets, or even twenty-four hours practical abstention from food. When digestive symptoms are severe and accompanied by paroxysms of pain it is probable that the glycosuria depends on a definite pancreatic lesion which calls for treatment. (See *Diseases of the Pancreas*.)

11. **Ocular Complications.**— Ophthalmoplegia due to neuritis has already been considered. For the treatment of cataract, the most frequent of the ocular complications, reference must be made to works on ophthalmic surgery. Retinitis may occur in simple diabetes, but is more likely to be met with when there is a kidney lesion as well. The treatment is that of the cause. Diabetic amblyopia due to a central scotoma is in my experience only met with in smokers. As the amount of tobacco consumed has sometimes been quite small, I conclude that the symptom is due to the action of combined toxins. Entire abstention from tobacco seems to be necessary in such cases. When tobacco amblyopia occurs in a moderate smoker suspect glycosuria.

12. **Diabetic Collapse.**—In some cases the patient may be suddenly attacked with alarming collapse. The extremities and the face become livid and the pulse becomes small and very frequent. The patient becomes drowsy and will probably die within a few hours, but there is no evidence of acetonuria. R. T. Williamson has called attention to the importance of this condition, which is generally attributed to myocardial degeneration, and should be treated on the same lines as acute heart failure from any other cause. The intravenous injection of a pint of saline containing $\frac{1}{250}$ gr. of strophanthin and oxygen inhalations are probably the best methods to adopt.

13. **Mental Complications.**—Most diabetics are irritable and many are unduly suspicious. Occasionally these symptoms may be intensified into delusions with suicidal or homicidal impulses, or the patient may become melancholic. Such cases should be treated on the ordinary lines of a toxic insanity. The treatment of the glycosuria must be persisted in.

14. **Pregnancy.**—Diabetes generally causes amenorrhœa and conception is rare. If it occurs the fœtus dies *in utero* in about two-thirds of the cases, often with hydramnios. The interests of the mother are therefore paramount when they conflict with those of the child. Pregnancy may be allowed to go to full term as long as the mother's condition improves under treatment and the bulk of the uterus is not excessive. But if the glycosuria remains at a high level, if there is hydramnios, or if other unsatisfactory symptoms occur the pregnancy should be terminated, especially if former pregnancies ended by the birth of a dead child. Naturally it must be clear that the glycosuria preceded the pregnancy, and that it is not merely the glycosuria or lactosuria of pregnancy. Even though pregnancy is well borne, the diabetes will probably get worse afterwards; it is therefore best avoided.

W. L. B.

DIABETES INSIPIDUS

Different causes may produce polyuria of the kind to which the name of Diabetes Insipidus has been applied. The recognition of this fact is essential to the proper treatment of what is really a symptom. A persistent polyuria without the presence of albumin or sugar may result from (1) syphilitic meningitis, especially of the base of the brain; (2) disease of the hypophysis cerebri; (3) a primary defect of the kidney which renders it incapable of secreting concentrated urine; (4) polydipsia.

1. The frequency with which syphilitic meningitis is responsible for diabetes insipidus makes it imperative that in every case Wassermann's reaction should be tried before treatment is undertaken. I have obtained a strongly positive reaction in a boy with diabetes insipidus who certainly presented no other stigmata of congenital syphilis. Meningitis affecting the interpeduncular space would be likely to irritate the hypophysis cerebri, so that this type is sometimes similar in its origin to the one to be described next, but is usually more amenable to treatment. Daily inunction of a drachm of mercurial ointment and administration of potassium iodide must be carried out. At the present time, the feeling is in favour of giving rather full doses of potassium iodide, *e. g.* 8 to 15 gr. or more three times a day for a fortnight at a time, with intervals of a fortnight without any.

As to the advisability of neosalvarsan in

conditions depending on cerebral and congenital syphilis, see the article on syphilis.

2. The cases of hypophyseal origin are the worst and most progressive because they usually depend upon a new growth. The head should be skiagraphed in all cases, great care being taken to get the rays exactly transverse to the clinoid processes. The best plan appears to be to place a bullet in each external acoustic meatus and to adjust the position of the head, and the direction of the rays, until the shadows of the bullets are accurately superposed. The cases which become drowsy and then comatose, with ocular disturbances, such as bi-temporal hemianopsia and optic atrophy, or where glycosuria ensues in the later stages, will almost certainly prove to be of hypophyseal origin. Cushing's experimental observations on this subject are of great importance. The pharmacological action of pituitrin is to raise the general blood pressure by vaso-constriction while dilating the renal vessels, thus causing diuresis. According to Schäfer, the effect of a second injection is more diuretic without general vaso-constriction, so that the effect of repeated injections is analogous to the condition seen in diabetes insipidus. Such cases are not likely to respond to treatment. If there is evidence of a progressive tumour of the hypophysis cerebri, operation would have to be considered as offering the only and that not a good chance in a grave disease.

As the condition is presumably due to over-secretion, there does not appear to be any use in giving extracts of the gland or of its adjuvant, the thyreoid. The internal secretion of the pancreas is opposed to that of the hypophysis as regards glycosuria, but I am not aware that pancreatic extract has proved of any benefit, though it might reasonably be given a trial in hypophyseal diabetes insipidus. Treatment must be mainly symptomatic, as described below. The sinister significance usually attached to diabetes insipidus is probably due to these hypophyseal cases, for the other forms of the disease are consistent with life and health for many years. It is quite probable that the temporary polyuria following head injuries is set up by irritation of the hypophysis cerebri, and the fact that over-secretion of this gland can be evoked by nervous stimuli may explain hysterical polyuria.

3. In the form associated with the primary defect in the kidneys, the patient is incapable of secreting urine of a normal concentration, so that he requires a much greater quantity of water to remove the normal products of metabolism. According to Meyer, the condition may be recognised by the reaction to the administration of 20 grm. (5 dr.) of sodium chloride, which will be excreted very slowly here, but not in the other types where the kidney, being sound, can respond by excreting it within twenty-four hours. In this renal type of the disease, the excretion of the ingested salt may take a considerable time, even some days. It will be noted that there is a resemblance between this condition and an interstitial nephritis in which the power of secreting concentrated urine and salt is also distinctly reduced, while the minute trace of albumen is hardly detected in such a large amount of fluid. Indeed, in some *post-mortem* records of diabetes insipidus, it is by no means clear that the condition of the kidney was really distinct from chronic interstitial nephritis. Observations of the blood pressure are badly needed; if this proves to be definitely raised, it provides an additional point of resemblance with interstitial nephritis. Meyer has introduced another interesting test for recognising this condition. Theocin-sodium-acetate increases the permeability of the kidney, and where this permeability is reduced for solids, the drug, by facilitating their excretion, does away with the necessity for further dilution of the urine. Therefore, though it ordinarily acts as a diuretic, here it merely raises the concentration of the urine without increasing the amount of fluid. Applying this test in the case of syphilitic origin, I found that theocin-sodium-acetate raised the excretion of water from 5,600 to 8000 c.c. It should be noted that the doses formerly recommended are now considered excessive, and that 2 gr. twice a day will probably be found sufficient. It follows that restriction of the ingested fluids is a futile and cruel procedure. The patient *must* excrete a dilute fluid, and, if fluid is not given to him, he must obtain it from his own tissues. He loses weight, and the output of nitrogen rises, showing that the deprivation of water is producing tissue breakdown. This increased excretion of nitrogen in turn demands more excretion of water. The appetite and the general health will soon suffer, while the distress from thirst becomes extreme.

But I am not yet satisfied that this type is entirely distinct from the hypophyseal form. In the syndrome of infantilism with interstitial nephritis and recrudescent rickets described by Morley Fletcher, the hypophysis cerebri may be enlarged and the condition approximates to this renal type of diabetes insipidus. Moreover, Saundby has pointed out that in diabetes insipidus the cause of death may be the gradual destruction of kidney substance producing uræmia.

Treatment should be directed towards diminishing the solids that have to be excreted by the kidneys, this being an important factor in producing the polyuria. To this end, the amount of salts should be rigidly restricted

and all meat extracts forbidden. The amount of protein should be reduced. The patient can be encouraged to make up with carbohydrates and fats, which will diminish his appetite for nitrogenous food, and meat should certainly not be allowed more than once a day, and then only in small quantities. Tea, coffee and alcohol should also be avoided.

4. If the Wassermann reaction is negative, if the skiagram of the skull is normal, and if 20 grm. of sodium chloride do not provoke well-marked diuresis while theocin-sodium-acetate does, the probability is that polyuria is secondary to the excess of fluid imbibed. Ralfe advised that if the fluid ingested and excreted approximately balanced, the amount of fluid drunk should be reduced by 2 pints; if this is followed by a fall in the urine excreted, the fluid drunk is reduced by another pint every third day, but, as soon as there is no more reduction in diuresis, the intake should not be restricted any further. It should be noted that this method was originally suggested for diabetes insipidus in general, but from the foregoing considerations it will be clear that it is only likely to meet with success in cases secondary to polydipsia.

Symptomatic Treatment.—While the origin of many cases remains obscure, much of our treatment must remain symptomatic. Acidulated drinks, or $\frac{1}{2}$ oz. of raw oatmeal stirred into 2 pints of water and flavoured with lemon are pleasant. During any period of restriction of fluid the patient may temporarily alleviate thirst by frequently rinsing the mouth out with water without swallowing it. I have found the sucking of acid drops to increase the thirst. A small dose, $\frac{1}{20}$ gr., of pilocarpin may relieve the dryness of the mouth. Whatever the origin of the case, tea, coffee, alcohol and salt are inadvisable.

The drug which has the greatest reputation in the symptomatic treatment is valerian. As much as $\frac{1}{2}$ oz. of the tincture has been given four times a day, with apparently good results. It may be reinforced with advantage by 5–10 min. of tincture of cannabis indica, and some bromide of ammonium. Valerianate of zinc has also been advocated in large doses, such as 15 gr. gradually increasing to 30, three times a day. I have never used it in such large amounts, but with 8 gr. in the day I have noted that while the output falls, the intake rises, and I suspect that the drug acts largely by causing retention of water in the tissues. Ergot (10 min. of the fluid extract three times daily) may cause temporary benefit, but a careful look-out must be kept for symptoms of ergotism. Arsenic and iron are useful adjuvants as tonics. Electrical treatment has been recommended by Robertson in the form of the constant current, with the positive pole at the back of the head, and the negative passed along the floor of the nose until the cervical spine is reached. Starting with a current of $\frac{1}{2}$ ma., this is gradually increased to 5 ma. The duration of the application is at first one minute, increased every second or third day until it is used for five or six minutes. A seven weeks' course is advised.

But before treatment can be put on a really satisfactory basis more complete observations will have to be made in each case to determine the origin of the symptoms. At the present time, the theory of a direct or indirect overaction of the hypophysis cerebri seems to offer the best clue. W. L. B.

GOUT

The treatment of gout at the present time reflects the changing views as to its pathology. Formerly gout was regarded as simply due to retention of the uric acid derived from the food which became deposited as insoluble biurate of soda in those peripheral structures where circulation was sluggish and the proportion of sodium high. The inflammatory changes in the joints were regarded merely as the result of mechanical irritation by the biurate crystals, while the cardio-vascular changes were attributed to uric acid increasing the viscosity of the blood, thereby impeding the circulation. On this view, the rational treatment was considered to be abstention from the purin bodies in the food which produce uric acid and administration of drugs credited with being uric acid solvents. Three main facts have led to a modification in this point of view: (1) mere excess of uric acid will not cause gout, for in leukæmia the amount of uric acid formed is about ten times the normal, yet gout does not follow. (2) In the normal animal the liver can destroy uric acid rapidly, so that even if the kidneys are prevented from excreting properly no retention of uric acid occurs. Therefore, in gout we have to postulate a failure in the uricolytic ferments of the liver. This may possibly be the result of an intestinal intoxication. (3) However strictly the intake may be limited, the body can still produce uric acid in considerable quantities. The endogenous formation of purins plays a larger part in the pathology of gout than was formerly suspected. As Sir James Goodhart says: "Though you exclude absolutely all uric-acid-forming food . . . you may wither up your patient into a shrivelled, juiceless, prematurely aged being, and there will yet, under favourable conditions, be squeezed out of his tissues enough uric acid to form a large deposit of red crystalline matter in his urine." There is apparently an inability to katabolise purins whether from the food or in the tissues,

probably due to hepatic insufficiency, just as in cystinuria or alkaptonuria. But unlike these, the insufficiency does not show itself from birth, although there is undoubted hereditary transmission.

"Gout has tended to become prevalent among peoples who, after periods of stress and struggle, have attained to conditions of material well-being, who have aggregated into cities which become the centres of increasing luxury and more elaborate civilisation" (Garrod). Thus it was common in Imperial Rome. The history of the individual repeats that of the race, and gout is apt to occur in those who, after a strenuous earlier life with plenty of exercise, settle down to a sedentary and comfortable middle age with abundance of good living. There is a general agreement that gout is becoming less frequent at the present time, even allowing for the fact that many diseases formerly labelled gouty are no longer considered so. Greater moderation in eating and especially in drinking the heavier forms of alcohol, a more open-air life with rational physical exercise are probably the principal factors in this decrease.

The treatment of the gouty paroxysm is still frankly empirical, while an attempt is made to place the treatment of the gouty state on a rational basis. For that reason we will deal with the latter first, though it must be admitted that many of the means adopted still lack rational sanction.

1. Treatment of the Gouty State

The gouty subject should be encouraged to take up some form of out-door exercise and sufficient occupations or hobbies to prevent the morbid introspection to which he is prone. Worry is a fertile cause of attacks in some, and I have known heads of families who were carefully screened from anxieties by the other members in self-defence, for if they were not so sheltered they could always revenge themselves by an attack of gout. Heavy dinners and late hours should be forbidden. Careful attention will, of course, be paid to the state of the bowels. For this purpose the Compound Colocynth pill or a pill containing 2 gr. of iridin, 1 gr. of euonymin and extract of hyoscyamus q.s. may be given. A routine use of an aperient water may be indicated every morning.

Dietetic Treatment.—Here the purin-containing foods claim our consideration first. Purins contain the group C_5N_4, and uric acid is merely one of the more abundant and more highly oxidised of them. The urinary purins are derived from (1) the food, either as (*a*) free purins, xanthin and hypoxanthin in meat juices, (*b*) bound purins from the nucleoproteins of the cell nuclei, and (*c*) methyl-purins in tea, coffee and cocoa, (2) endogenous purins formed within the body chiefly by the muscles and leucocytes. It follows that the more cells the food contains the more purin will it yield. The accompanying table from Walker Hall's analyses will show the relative amounts of purins in ordinary articles of diet.

	Purins in Grains per pound.
Fish :	
Cod	4·07
Salmon	8·15
Meat :	
Mutton	6·75
Beef	7·96–14·45
Chicken	9·06
Liver	19·26
Sweetbread	70·43
Eggs and cheese	almost 0
Vegetables :	
White bread, rice, cabbage, cauliflower, lettuce	0
Potatoes	0·14
Asparagus	1·5
Peas	2·54
Oatmeal	3·46
Beans	4·16
Beverages :	Purins in Grains per pint.
Wines	0
Milk	0·0014
Beer	1·09–1·27
	Methyl-purins Grains per teacup.
Tea, China	0·75
Tea, Ceylon	1·21
Coffee	1·7

From this it will be noted that milk, eggs, cheese, white bread, butter, rice and most vegetables except the pulses are practically free from purins. On the other hand, it will be seen that the usual distinction drawn between red and white meat is entirely fallacious if it is intended, as it presumably is, to refer to the amount of purins contained, for chicken contains more than mutton, while sweetbread is extremely rich in them. Luff maintains, nevertheless, that sweetbread is harmless, since its nuclein portion is only slightly absorbed. But it is certain that the administration of sweetbread to a healthy man is followed by a greatly increased excretion of uric acid, while this is much less pronounced in the case of a gouty subject. As Garrod well says: "If the knowledge which we possess does not justify us in pronouncing sweetbread to be

undesirable food for gouty people, we must admit that we are not yet in a position to give any advice on this subject on scientific, as distinguished from empirical, lines." Other internal organs, such as liver and kidney, are inadvisable on similar grounds.

Strong animal soups and meat extracts are definitely contra-indicated, as they contain purin bodies without a corresponding amount of nourishment.

It is usual to forbid gouty patients asparagus, presumably on account of the small quantity of purin which it contains, but considering that this only amounts to 1·5 gr. in a pound of asparagus, it is really negligible and, in my opinion, the diuretic effect of asparagus renders it quite a suitable vegetable for the gouty. Peas, oatmeal and beans do contain a definite amount of purin, and the last two had better be taken to a limited extent only.

In general terms leaves are better than roots so far as vegetables are concerned. Spinach may be allowed except when oxaluria is present. Fresh fruit such as pears, green figs, oranges and grapes may be allowed. The sweeter, richer fruits such as dates, are less suitable. Lemons may be allowed, for the citric acid which they contain will become bicarbonate in the blood and, therefore, does not cause acidity. Preserves are usually better avoided on account of the fermentation which has usually taken place. In spite of Linnæus's advocacy of strawberries, Garrod advises gouty patients to avoid them. There is no special reason to avoid sugar, as is usually done, unless there is a tendency to obesity. Fats have no real influence in gout except (1) as a factor in obesity; (2) as rendering food less digestible. Thus, when things are cooked in fat, they are likely to cause dyspepsia by inhibiting the secretion of gastric juice.

Beverages.—There can be little doubt that alcohol plays an important part in the production of gout, especially in the form of malt liquors, port and liqueurs. Sherry is injurious to some and champagne to others, although they do not contain purin bodies as beer does. The lighter white wines, such as still hock or moselle, may be taken when the patient is unwilling to do without alcohol either because he is accustomed to it or because he finds it a stimulant to digestion. Well-diluted whisky in moderation may be allowed for these reasons, but there is little doubt that every gouty person is decidedly better without alcohol at all. Tea and coffee are often forbidden on the ground that they contain methyl purins, but as they are excreted without being converted into uric acid, it seems a mistake to deprive the patient of these valuable stimulants. If they do not disagree with the digestion, they are not likely to increase the gouty symptoms. Cocoa, on the other hand, is too rich and fattening to be a suitable beverage, quite apart from its purin content. Hard water is frequently condemned though without any very clear reason. It is hardly necessary to point out that the "chalk stones" do not contain any calcium salts at all, and, therefore, there is no reason why a chalky water should increase them. Apart from its constipating effect, there is nothing in hard water to do a gouty patient harm. Mineral waters of all kinds have been freely used in the treatment of gout. In fact, the chemical constitution of various waters advised has been so widely different as to suggest that the active ingredient in them all has been the water. As Osler says: "Much of the humbuggery of the profession still lingers about mineral waters, more particularly about the so-called lithia waters." Still, not to take too sceptical an attitude of this subject, we may inquire into the most suitable springs for the purpose.

Spa and Bath Treatment. — The principal benefits appear to have been derived from (1) radio-active water, such as that of Bath or Buxton, (2) alkaline waters such as those of Vichy or Royat, and (3) sulphur-containing waters such as those of Harrogate, Llandrindod, Strathpeffer, or Aix-les-Bains, which presumably act by remedying the intestinal condition. But, in every case, a large share in the benefit must be ascribed to the regulated life and freedom from worry which is an essential part of spa treatment. Most spas are now fitted up with all sorts of mechanical and electrical aids to treatment, which, while they do not indicate any excessive faith in the efficacy of the springs on the part of the management, are a valuable aid to treatment. The various balneological measures which may be used in chronic arthritis are fully described in the article on *Chronic Diseases of the Joints* (q.v.). For further details of suitable spas the reader should consult the article on *Balneology and Climatology*.

Warm baths may be a help if the skin has ulcerated over the chalk stones, by dissolving some of the exposed biurate of soda. Thus, a 2 per cent. solution of potassium carbonate may be used quite warm in an arm bath, though not for long enough to make the surrounding tissues sodden. In addition to the other measures described under chronic diseases of the joints, ionisation may be a decided assistance. For this purpose lithium salts may be used on the positive pole and 2 per cent. salicylates or tincture of iodine on the negative. A much stronger current can be used with salicylate than with iodine. Another method is to employ 1 to 2·5 per cent. solution of sodium chloride on the negative pole, a current

of 5 milliamperes per square centimetre of surface being passed for twenty minutes. Such applications may be used once a fortnight.

Uric Acid Solvents. — Few drugs have any real action as solvents of uric acid in the tissues; our altered views on the significance of uric acid in gout also diminishes our ardour in trying to effect this.

Lithium salts held for long a high reputation for this purpose simply because lithium urate is much more soluble than the potassium or sodium salt. On chemical grounds it is impossible for this claim to be substantiated. Chemical action is determined both by the mass and avidity of the various interacting bodies and also by the law that in any mixture of acid and bases it is the insoluble combination that occurs. The few grains of lithia which can be introduced into the body cannot possibly contend with all the sodium present there, which, in addition to having the advantages of mass reaction, forms the less soluble salt. Moreover, if enough lithium could be introduced for this purpose, it would be definitely poisonous. The only value of lithia water is in the water itself.

Piperazin had a vogue some years ago until it was shown that in the quantities which could be taken it had no solvent action in the body although it had in the test-tube. This is explained by the fact that when several salts are added to uric acid in a test-tube the solvent action of piperazin is much reduced. We may conclude that the salts in the blood act in the same way.

Lycetol and lysidin, which are closely allied to piperazin, have failed for similar reasons.

Urotropin was advocated on the grounds that the formaldehyde it gives rise to forms a soluble urate. In the body, however, it does not increase the uric acid output to any real extent.

Salicylic Acid and its derivatives, on the other hand, definitely increase and may double the uric acid output in the normal individual on a purin-free diet. It may even have this effect after five years of a purin-free diet. This can scarcely be due to washing out of retained uric acid, for, in view of its rapid destruction normally by the liver, such retention can hardly occur. As there is not a marked loss of weight when salicylates are given, the doubled output cannot be due to doubled breakdown of the tissues. By a process of exclusion we are forced to the view that it actually causes a synthetic production of purins, though there is no direct evidence of this. It would certainly be curious if, in our anxiety to wash out uric acid, we were really increasing its endogenous production.

Thyminic Acid (solurol) was recommended by Minkowski in the belief that uric acid is normally carried in solution combined with this organic acid. The number of recorded successes with the drug remains very small, however, and its use appears to be making but little headway.

Atophan (phenylchinolin-carbonic acid) is the most recent addition to the uric acid solvents. That it will, in some cases, increase the uric acid output to an extraordinary degree is certain. When taken by a healthy individual the excretion of uric acid, even on a purin-free diet, rises at once, and then slowly falls, returning to normal by the third or fourth day. When uric acid is injected into a normal man its excretion is spread over several days, and the total amount injected is not recovered; but if the injection is given during a course of atophan the whole of the uric acid is completely excreted within twenty-four hours. According to Walker Hall, the same results are obtained in a gouty individual, so that, under the influence of this drug, the gouty and the healthy renal cell appear to excrete just the same amount of uric acid. Its administration appears to shorten the acute stage of gout, and is accompanied by increased uric acid output. So far as it goes this might be held to support the retention theory; more probably, however, both retention and constitutional disturbances are due to the same unknown perversion of metabolism, and the drug affects the endogenous formation of purins. Atophan is put up in tablets containing seven and a half gr., four to six of which should be given in a day broken up in plenty of water. Weintraud, who warmly recommends it, advises full doses of sodium bicarbonate at the same time, such as half an ounce on the first day and a drachm and a half on subsequent days. The method is well worth a trial, both in acute and chronic gout. In the latter I have had considerable success by giving atophan for one week in each month. It is obviously contra-indicated in urinary calculus and gravel. In view of the insolubility of the sodium salts and their abundance in the body, it would appear more rational to give some at least of the alkali in the form of potassium salts, and this I have done. For a similar reason Sir W. Roberts advised patients to restrict their use of table salt, substituting potassium chloride as far as possible. Perhaps we might go further and check the addition of table salt to the food altogether.

The *alkaline treatment* of gout has little experimental evidence in its support. In severe diabetes there is often a definite diminution in the alkalinity of the blood, but this is not the type of glycosuria in which gouty symptoms occur. Sir William Roberts, although he said of himself that "few practi-

tioners had employed alkaline remedies in gout with more determination," finally decided against their utility.

Other drugs which have had considerable vogue in the treatment of chronic gout are potassium iodide and guaiacum. They may be given a trial, but it would seem that many of the successes recorded were in cases which were more probably rheumatoid arthritis.

2. Treatment of the Gouty Paroxysm

Besides the general treatment suitable to a febrile state, the affected joints should be raised and protected. Application of cold to or leeching of the joints is to be avoided. A hot lotion containing an ounce each of bicarbonate of soda, glycerine and tincture of opium in 12 ounces of water will afford much relief, though, in deference to the pharmacologists who deny the local effects of opium, this might be omitted. Internally, nothing is so effective as *colchicum;* we do not understand its action, though, as it causes a temporary diminution in the number of leucocytes, it may lessen the production of endogenous uric acid. The subsequent return of the leucocytes would account for the failure of the drug to exert a prolonged influence. Ten minims of the Vinum Colchici or the Tr. Colchici Semin. should be given every four hours for a few days. It is usually combined with 10 gr. of *carbonate of magnesia* or *salicylate of soda*. The latter drug cannot be justified rationally in view of its apparent action in increasing the endogenous uric acid, though empirically it seems to relieve pain. Caution must be exercised with colchicum, as it causes purging or faintness in some patients. If it cannot be borne, *atophan* may be substituted, and, in any case, it is worth while to give this drug when the colchicum is stopped.

Citarin, a compound of formaldehyde and citric acid, has been recommended in doses of 15–30 gr. three times a day. It is incompatible with alkalis. *Potassium citrate* is often useful as a diuretic which also renders the urine less acid. If none of the above drugs suit the case, a mixture of *iodide and bromide of potassium* may be tried. If the kidneys are sound, 10–15 gr. of *Dover's powder* may be given at night. It is well to avoid all meat, meat juices and alcohol during the acute stage.

3. Treatment of Suppressed and Irregular Gout

Almost every condition characteristic of the middle and degenerative periods of life have been thus described, but the evidence that they are really gouty in nature is often quite unsatisfactory. Suppressed or retrocedent gout is a name applied to alarming and often fatal symptoms referable to the alimentary canal (pain, vomiting and diarrhœa), the cardiovascular system (dyspnœa, palpitations, syncopal and anginal attacks), and the nervous system (headache, twitchings, delirium and coma). They are said to come on as a result of a chilling of or the direct application of cold to affected joints, and they certainly may be accompanied by a diminution of the local signs. It can hardly be doubted, however, that they are essentially uræmic in character and should be treated as such. The following manifestations are usually regarded as irregular gout—

1. *Cutaneous System.*—Eczema. On this point Adamson says that "one may see hundreds of cases of eczema without meeting with a case of gout; in fact, a gouty patient is practically unknown in a skin clinic." Clearly, then, the treatment should be that of eczema (*q.v.*). Dupuytren's contraction of the palmar fascia has no proved affinities with gout.

2. *Special Senses.*—Episcleritis and conjunctivitis (the "hot itching eye" of gout), iritis and glaucoma, have all been referred to a gouty origin. For their treatment reference must be made to a work on ophthalmic surgery.

3. *Nervous System.*—Migraine, neuralgia, neuritis and sciatica have been attributed to gout with varying degrees of probability. The treatment is that of chronic gout in addition to that of the local conditions (*q.v.*).

4. *Respiratory System.*—We may observe that true spasmodic asthma is more likely to occur in gouty families rather than in patients with gout. Any one who has chronic bronchitis long enough will become emphysematous, when a secondary asthma is liable to follow. From implication of the heart or kidneys, so-called cardiac or uræmic asthma may result, which is, of course, an entirely different thing. In each of these cases the treatment is that of the local conditions rather than of gout.

5. *Circulatory System.*—Gout may set up interstitial nephritis and atheroma with their attendant effects on the cardio-vascular system. For the prophylactic and early treatment of such conditions see the article on *Chronic Interstitial Nephritis*. Recurrent phlebitis, especially in the legs, is often attributed to gout. It is quite as often due, in all probability, to infections and intoxications from various sources, especially the alimentary tract (see article on *Intestinal Intoxications*).

6. *Digestive System.*—"Bilious attacks" are common, in which the tongue is furred, the breath offensive and the bowels constipated: the liver is said to be sluggish, but certainly some of these attacks are due to B. coli infections, as are the "gouty" cystitis and urethritis.

7. For "*gouty*" *glycosuria* see the article on *Diabetes*.

W. L. B.

OBESITY

The term obesity includes four distinct clinical types, namely: ordinary obesity, anæmic obesity, toxic obesity, and internal secretory obesity. Treatment will inevitably depend upon a recognition of the predisposing cause. *Ordinary obesity*, or, as it is sometimes inelegantly termed, "the middle-aged spread," may be regarded as the outcome of a lack of balance between the physiological intake and output; in other words, the patient is one who eats too well or works too little, or both. *Anæmic obesity* is frequently seen in chlorosis and after profuse hæmorrhage from whatever cause; it depends upon an insufficiency of hæmoglobin and consequently of oxygen, whereby the metabolism of fats is reduced. *Toxic obesity* is due to the presence either of substances which reduce metabolism, such as alcohol, mercury, arsenic, or of poisons such as that of typhoid fever, whose action it is to exhaust the metabolic activities. *Internal secretory obesity* is the outcome of a disturbance of the balance which subsists between the various internal secretory glands. Transient forms of such obesity are sometimes seen at puberty, and are induced by factors such as marriage, maternity, lactation. But the class includes forms, such as the obesity of the menopause, adiposis dolorosa (Dercum's disease), myxœdema, and lipomatosis universalis asexualis, which are persistent in their nature although they may be induced to yield to appropriate treatment.

Ordinary Obesity.—Drugs play but a small part in the treatment of ordinary obesity; it is largely a matter of exercise and diet. Various systems of diet are in vogue, and of these Banting's and Salisbury's are undoubtedly the best. By these methods the fats and carbohydrates are reduced, the nitrogenous elements are very much increased, and large quantities of water are consumed. Although frequently attended by considerable success, it must be borne in mind that these measures place an enormous strain upon the kidneys, and that the ingestion of nitrogenous substances in large quantities tends to the production of high blood pressure and consequent arteriosclerosis. Before resorting to such vigorous treatment the physician should in all cases assure himself that the condition of the patient in these directions leaves nothing to be desired. Where this assurance is lacking, treatment must be confined to limiting the general intake, especially of fats and alcohol, at the same time increasing the output by suitable means, notably massage, Turkish baths, special exercises, and exercise in the open air. Undoubtedly the best method of managing these patients is by a course of treatment at a spa, such as Vichy or Marienbad.

Exercises.—With the approach of middle life, though there may be no tendency on the part of the individual to eat more, there is almost certainly an inclination to do less. For this reason advancing age is in many instances accompanied by an increasing fleshiness, the deposition of fat being usually most marked in the region of the abdomen. The chief agent in effecting oxidation is admittedly muscular exercise, and it is a fact, though one which is not sufficiently recognised, that fat is very readily deposited in the neighbourhood of relaxed and atrophied muscles. Now it is just the muscles of the anterior abdominal wall for which the usual forms of exercise, such as walking and golf, undertaken by the man of middle age, provide little or no exertion. As a consequence, these muscles become atrophied and flaccid, and the figure acquires the dreaded aldermanic curve. It is necessary that a determined effort should be made to restore to these muscles something of their original tone. Exercise in the open air, although recommended upon general principles, is useless as a means of reducing local adiposity; this will yield only to local exercises, of which the following will be found to be very efficacious. They should be performed immediately upon rising, with the window open and wearing as little clothing as possible. The patient lies flat on his back upon the floor with a weight upon his feet to prevent their rising from the floor. The feet should be thrust under the opened bottom drawer of the chest of drawers. With his arms folded on his chest the patient pulls himself into a sitting posture by means of his abdominal muscles, taking care not to bend the knees. This should be done three or four times, increasing the number with practice until the manœuvre can be performed seven or eight times in succession without undue fatigue. When this can be accomplished the patient should attempt to perform the same exercise, but with this difference, that the arms are extended above the head in a line with the body. Care must be taken that the arms do not advance beyond the line of the trunk. This exercise is more difficult than the first; it should, however, be persevered with until it can be performed eight to ten times in succession. Next, releasing his feet and still lying upon his back, with arms crossed upon his chest, the patient should endeavour to raise both legs from the floor without bending the knees, until they form a line at right angles to the trunk. Other exercises which may be attempted are: (*a*) To touch the toes without bending the knees; (*b*) Extended on the floor with head and heels touching the ground and arms crossed upon the chest, to raise the trunk from the ground in the manner of an arch by means of the trunk muscles alone. These

exercises should be performed slowly and deliberately, and as proficiency is attained the number of times they are performed in succession should be increased. Their continued and regular practice is followed by a reduction of "front" and a reappearance of the waistline to a degree which is sometimes positively astonishing.

Massage and Zander and Swedish exercises are to be recommended, but they must be employed with discretion. Much harm has been done, resulting in cases of hernia and other abdominal complaints, by the employment of over-drastic methods.

Turkish baths and electric-light baths promote metabolism and are therefore valuable adjuncts to other treatment. There is no class of patient which responds more readily to spa treatment than the ordinarily obese. Not only are the general principles of the treatment, such as diet, massage, exercise and baths, more easily applied and more efficiently enforced than at home, but the patient receives a mental stimulus from the regular life and changed surroundings which plays no small part in effecting a cure. The obese tend to be indolent in mind as they are lethargic in body. Mental activity is a great promoter of oxidation, and for this reason a factor which ensures distraction and employment of mind has a therapeutic value which it is difficult to over-estimate. It must be borne in mind, however, that the success of spa treatment depends in the first instance upon the right choice of a spa. Marienbad, Carlsbad, Homburg, Kissingen, Vichy, Vittel, Evian, Aix-les-Bains, Brides-les-Bains are all indicated.

Drugs play but a minor part in the therapeutics of obesity, and in the large majority of cases they are unnecessary. Their rôle is confined to promoting metabolism and to assisting the functions of the excretory organs. In no case should a direct action upon the adipose tissue be aimed at, and drugs such as iodide of potassium and thyreoid extract should be left severely alone. The marked effect of thyreoid extract in reducing adiposity is only too well known; its harmful influence in other directions is, unfortunately, less well recognised.

Although in its graver forms it is more likely to produce emaciation, a very common cause of obesity is chronic constipation. A good method of managing these cases is by a course of sulphate of magnesia, 5 gr. of blue pill being given once a week. But the use of paraffin oil, which is now so general, if it be really persevered with, is certainly the best means of overcoming constipation. Dyspeptics may be treated with soda and bismuth, and all obese patients will derive benefit from a diuretic, such as ½ oz. of infusion of buchu given in half a tumbler of Evian water half an hour before each meal.

Diet.—Whatever attitude the physician may adopt in regard to the diet of an obese patient, there are two directions in which no latitude is permissible. The intake of common salt must be severely limited, and no fluids should be allowed with meals. During the first fortnight salt should be eliminated altogether from the dietary; later on it may be used sparingly, but the amount should never exceed 160 gr. a day. By this measure a double object is achieved. In the first place, the amount of HCl in the gastric secretion is reduced and appetite is in consequence less keen; moreover, food without salt being unpalatable, the patient is never tempted to eat to excess. In the second place, the ingestion of salt favours that accumulation and stagnation of fluid in the lymph spaces which is so prejudicial to efficient metabolism. Fluids may be taken half an hour before or an hour after meals, never with them. The point is one which needs emphasis, and neglect to supply a patient with precise directions may lead to disappointment in the results of an otherwise rational treatment.

The Vegetarian System is a favourite one in France, and it has this very distinct advantage: it may be employed without prejudice in cases where the more drastic regimes, such as Banting's and Salisbury's, are excluded by reason of the state of the patient's arteries and kidneys. The diet is almost exclusively composed of green vegetables, such as cabbage, cauliflower, spinach, etc., reinforced by eggs, milk and cheese. It has the merit of providing food in a quantity sufficient to stay the patient's appetite, but of a quality so low in nutritive powers that weight is rapidly lost. The drawback to the system lies in the fact that unless the food values are carefully controlled, the nitrogenous intake is liable to be inadequate. Moreover, many patients have so great a distaste for a vegetarian dietary that to enforce it is to impose upon them a hardship.

Banting's, Salisbury's and Ebstein's systems are fully described in the textbooks of dietetics (*Textbook of Diet and Dietetics*, edited by G. A. Sutherland). The following is a dietary of moderate severity which should produce a reduction of about 1 lb. per week.

Dietary. 8 *a.m.*—A tumbler of hot water, sipped, to which some fresh lemon-juice may be added.

Breakfast. 8.15 *a.m.*—One small cup of tea or coffee sweetened with saxin or saccharin; no cream, no milk; 1 oz. dry toast; no butter; 4 to 6 oz. of lean grilled steak, chop or kidney, lean cold tongue, chicken, game, grilled or boiled sole, plaice, cod, turbot, brill, haddock or whiting.

1 *p.m.*—Three-quarters of a tumbler of Evian, Vittel or Vichy water.

Lunch: 1.30 *p.m.*—3 to 4 oz. of lean beef, mutton, lamb, chicken, game, hot or cold, roast or boiled; gravy must be free from fat; 4 oz. of any vegetable as given below plainly boiled without butter, lard or oil; a baked apple, or 2 to 3 oz. of baked cherries or gooseberries, sweetened with saxin or saccharine only; salad, if taken, must be without oil or beetroot; two to three Wine Oliver biscuits; 2 oz. of toast; one glass of light wine, red or white; small cup of coffee, without sugar, milk or cream, but sweetened with saxin or saccharin.

5 *to* 6 *p.m.*—A cup or two of tea without milk or sugar and one Wine Oliver biscuit; half an hour before dinner three-quarters of a tumbler of any of the above-mentioned waters.

Dinner.—3 to 4 oz. of any fish, as at breakfast, and 4 oz. of any meat, as at lunch; if chicken or game is taken it must be without bread sauce or crumbs; if less fish is taken the meat may be increased proportionately; 4 to 6 oz. of any vegetable as mentioned below, and 3 to 4 oz. of baked or stewed apples, rhubarb, cherries, or gooseberries, sweetened with saxin or saccharin only; salad and biscuit as at lunch; 2 oz. of toast; wine as at lunch; a cup of black coffee with saxin or saccharin.

A cup of beef-tea may be taken at bedtime, but a tumblerful of any of the above-mentioned waters is preferable.

Condiments Allowed.—Worcester and anchovy sauces; ketchup, pepper, mustard, vinegar, walnut pickle, horse-radish; not more than 160 gr. of salt may be taken per diem.

Salads and Vegetables Allowed.—Watercress, radishes, lettuce, cucumber, mustard and cress, spinach, asparagus, celery, brussels sprouts, cabbage of all kinds, cauliflower, broccoli, sea or Scotch kale, vegetable marrow, kidney or French beans, tomatoes, artichokes, endive, sorrel, salsify.

Anything not mentioned above may be assumed to be forbidden.

It is not the writer's intention to enter here into the details of the treatment of *Anæmic Obesity* or of *Toxic Obesity*. A recognition of the underlying cause points inevitably to the course which should be adopted.

Internal Secretory Obesity.—That a disturbance of the balance which subsists between the functions of the internal secretory glands is a cause of well-marked metabolic derangement has long been known. Much has been written upon the subject, more especially by physicians of the French school, but in the present imperfect state of our knowledge it is difficult to lay down definite lines for the pursuance of treatment. It is important that the physician should possess a clear view of the manner in which these glands act and react upon one another, for such knowledge alone will provide him with the key to the treatment of obesity arising from internal secretory derangement.

It is well known to breeders of animals that suppression of the activities of the sexual glands leads to an increased deposition of fat; hence the custom of castrating animals which are to be fattened for market. This rule holds good in the case of man and is applicable to individuals of both sexes. The pathological obesity of children, cases such as are seen in abundance at spas of the Salines-Moutiers class, is invariably associated with deficient development of the genital organs. Examination will show that obese boys possess testicles of the infantile type. That cessation of sexual activity leads to increased adiposity in the female is shown by the results of double ovariotomy, while the obesity of the menopause is a condition with which every one is familiar. Insufficiency, which is short of complete absence, either of the thyreoid or the hypophyseal secretion frequently results in the deposit of mucin in the tissues in quantities so large that a condition resembling general obesity is produced. Such conditions are lipomatosis universalis asexualis, now more generally known as Fröhlich's syndrome, and adiposis dolorosa (Dercum's disease). *Fröhlich's syndrome* is believed to be the outcome of hypophyseal insufficiency. It is common to both sexes and may make its appearance before or after puberty. It is characterised by pseudo-obesity of very pronounced type; where the onset is before puberty, by skeletal undergrowth; and by complete sexual impotence, the genitals either remaining infantile or reverting to the infantile type. The prognosis is bad and a rational method of treatment has not as yet been evolved. Pituitary extract (anterior lobe) has, however, done good in some cases, and should be tried. *Adiposis dolorosa* is a disease of middle life confined almost exclusively to women and appearing at or after the menopause. Its origin is obscure, but it is believed to be the outcome of some type of thyreoid inadequacy, and it has been associated with hypophyseal tumour. There are four stigmata of the disease, namely: adiposity, spontaneous pains with tenderness, muscular weakness, and psychic manifestations. The onset is gradual. There is frequently extreme general obesity with irregular fatty tumours; nodular raised areas appear which are soft, painful and tender; these never affect the face, hands or feet. Pain is spontaneous, and may be elicited by pressure; it is probably due to interstitial neuritis of the nerves of the adipose tissue. Prognosis is good as to life, but bad as to recovery. Treatment is almost entirely confined to relief of the symptoms. Thyreoid extract should always be tried, and hypophyseal has been known to afford a measure of relief.

So little is at present known of the manner in which the ductless glands react upon one another that it is difficult to say with certainty which of them plays the leading part in the production of obesity. For this reason it is the height of unwisdom to administer extracts of the glands with the sole object of reducing adiposity. Thyreoid extract should never be given unless, in addition to obesity, the patient shows signs of thyreoid inadequacy. Where a glandular therapy is deemed expedient there are two points which should be kept well in mind; one, that the amount of thyreoid usually given is many times too large; the other, that the amount of hypophyseal extract is usually much too small. The initial dose of thyreoid for a patient suffering from obesity should never exceed ½ gr. of the dried extract twice daily, and even then a careful watch should be kept for signs of intolerance. Hypophyseal extract given by the mouth in doses of 8 to 10 gr. per diem will be found to have a pronounced effect in stimulating the unstriped muscular tissue and favouring general metabolism. Although the extract, when given by subcutaneous injection, raises the blood pressure very notably, this effect appears to be lacking when the drug is given by the mouth.

Prof. Bergonié, of Paris, advocates a system of general electrical muscular exercise with a view of promoting metabolism, and thus of reducing obesity. The system requires a special apparatus which is now installed in various institutions in the large cities and in most of the spas. The results appear to be satisfactory in a fair number of cases. L. W.

RICKETS

Rickets is a disease of general nutrition affecting infants, and, to a less extent, older children, and producing characteristic changes in the bones. In considering its treatment the actual symptoms and signs of the active period of the disease, which is usually short, must be clearly differentiated from the resulting deformities which may persist throughout life. In judging whether a child has rickets in an active stage or whether the disease is quiet, it is necessary to look not only for the presence of the general symptoms, but also for those changes in the bones which are characteristic of the active period of the disease.

Amongst the general symptoms which indicate that the disease is still progressing the most important are abundant sweating of the head, muscular weakness, restlessness and constipation. The characteristic bone changes are those which occur at the epiphyseal ends of the long bones and at the costo-chondral junctions, the latter of course being the growing epiphyseal ends of the ribs. These changes give rise to the enlargement of the epiphyseal regions and to the beading of the ribs which constitute so characteristic a feature of rickets, and which should be accepted as evidence that the disease is still progressing.

This external enlargement of the epiphyseal regions persists, however, for some time after the actual pathological changes have ceased. A more accurate determination of the condition of the epiphyseal cartilages may be made by examining a skiagram. The latter, in active rickets, shows the widening of the cartilage in both directions, and a cup-shaped end to the diaphysis. These appearances alter very rapidly when the active disease ceases, the cartilage interval shrinking to its normal extent and the end of the diaphysis becoming straight and transverse.

Judged by the criterion of a skiagraph, rickets may be said to arise in the second six months of life, and to persist commonly in the active stage until the age of eighteen months to two years. During the third year active rickets is still frequently found, but after this it becomes rapidly less common. Very rarely it persists beyond the age of five, occasionally, however, continuing to the age of eight, nine or even older. Such a condition is properly called "Continued Rickets."

Occasionally the child appears well for a time, and then, owing to alteration in the surroundings or diet, the disease reappears, the characteristic epiphyseal changes returning. This condition may be called "Recrudescent Rickets." Very rarely older children at ages of from ten or twelve to sixteen or eighteen years, are found with rickets which is typical in all respects, the general lassitude and restlessness, muscular weakness and sweating being present, and the epiphyseal changes characteristic. Such cases are properly called "Adolescent Rickets." It is, however, very difficult, if not impossible, to prove that the disease in them is not a recrudescence of an earlier attack.

The period of activity of rickets must then be regarded as variable, and the criterion of its cure should be taken to be the disappearance of the characteristic bone changes. As a rule it is sufficient to judge of these by clinical observations, but in cases in which the enlargement of the epiphyseal regions persists after three or four months of careful treatment, it is advisable to confirm the opinion founded on clinical grounds by means of a skiagraph. The changes occurring at the epiphyseal lines are of course not the only alterations in the bones in active rickets. The subperiosteal and the endosteal growth of bone are also defective. so that the bones are softened throughout, but these changes are not easily demonstrable in

skiagraphs. After recovery such bones as are curved often become thickened and buttressed on the side of the concavity. This buttressing may sometimes yield evidence that the disease has been arrested.

Treatment may be divided into Preventive and Curative, and the latter further considered under general hygiene, diet, drug treatment and the treatment of deformities.

The Prevention of Rickets must depend on the adoption of a proper diet for infants. The disease never manifests itself during the first six or seven months of life in children who are breast-fed, and it is rare in children who have been suckled for twelve or even fifteen months. Breast-feeding must, therefore, be included as one of the important means of prevention. After weaning the one causative factor that is certain is the absence of a sufficiency of fat and protein and the presence of an excess of carbohydrates in the food. Severe rickets is far more common in cities where the mothers work, wean their children early, and substitute starchy foods for milk. The use of condensed milks, which are deficient in soluble protein and usually in fat, and which contain much additional sugar, is a further important causative factor.

But errors of feeding are not the sole cause. The general surroundings of the child are important, rickets being more common and more severe in slum districts where the children are poorly, and often improperly, clad, and where the supply of light and air is defective. Occasionally the whole of a family suffer from severe rickets, the younger children being, as a rule, the more affected, and it is often difficult in such cases to see how the food and surroundings differ from those of neighbouring families in which the children have escaped or have suffered from a mild attack. In fact, there is sometimes a family tendency to suffer from the disease, which cannot at present be explained.

Very occasionally in cases of continued rickets the disease persists for years, even when the child is amongst the very best hygienic surroundings, and is most carefully fed. In such cases some additional visceral disease may be present, and should be looked for. In such children a defect of the kidneys is sometimes present, giving rise to a "Renal Type" of Infantilism which is associated with rickety changes at the epiphyseal lines and with bone deformities. This condition is liable to be mistaken for ordinary uncomplicated rickets; the distinction is important, for, if operative treatment be undertaken for the deformities, the renal insufficiency may lead to a fatal result.

Diet.—The principles of arranging a diet for a child suffering from rickets have already been mentioned; they consist in the addition to the food of extra protein and fat, and the subtraction of carbohydrate particularly in the form of unaltered starch. Further, the feeds or meals must be kept regular in time, and biscuits, cakes and sweets, between meals must be forbidden. The chief food should be fresh cows'-milk, which should not be sterilised or boiled. As children are generally over a year old when they come under treatment, milk-puddings, fresh meat, eggs and fish may be added, and such fat as that of bacon. In older children green vegetables should also be ordered. Potatoes, biscuits, cakes, buns, sweets and condensed milk, should be forbidden, also patent foods, except those known not to contain an excess of starch. Bread should be given in moderate quantities, best in the form of toast and stale crust.

Drugs are of comparatively little value, cod-liver oil and malt, and iron in the form of phosphates are useful, especially amongst the poorer patients, who may find it difficult to get a really adequate supply of proper foods. These drugs should be looked upon as additions to the diet, furnishing certain elements which might otherwise be insufficient.

A child with rickets in whom the diet is corrected and the surroundings not excessively bad, should be cured of the active disease in three months, that is to say, skiagraphs at that time should no longer show the characteristics of activity. A little later, after four or five months at the latest, the external enlargement of the epiphyses and the beading of the ribs should disappear. If the child is not cured as rapidly as this, the home and surroundings must be carefully investigated, and, if necessary, the child should be sent away out of the town, or away from its home for two months. If the disease still continues, a very careful investigation of the patient must be made, in particular any septic focus, such as decayed teeth, must be removed, chronic gastro-intestinal disturbance looked for, and the amount and constitution of the urine investigated. As already stated, very occasionally the active process will persist in spite of every form of treatment. Provided, however, there is no reason to suspect renal disease, it may be confidently predicted that eventually the disease will undergo a spontaneous cure.

Prevention and Treatment of Deformities in Rickets.—Although the bones in rickets are soft, they do not bend unless they are subjected to some more or less continual pressure. Every rickety deformity has, in fact, a mechanical, in addition to the pathological, cause. In considering the prevention and treatment of these deformities it is essential in every case

to inquire into their mechanical cause, and to attempt to counteract it. It must also be remembered that in the majority of cases the bones will be well consolidated after three or four months' treatment, and that the deformities are not likely to progress seriously during that time.

The common alterations in the shape of the chest, Harrison's sulcus and the keeled sternum, are due to some inspiratory obstruction acting in conjunction with the rickety processes. The only method of preventing their increase consists in the removal of any obstruction such as that due to adenoids, and the treatment of the chronic bronchitis that is so common in rickety children.

The spinal deformities, although uncommon, are important, for if any considerable kyphosis or scoliosis has once arisen, the weight of the upper part of the trunk in the standing or sitting position will tend to its increase, even after the active rickety process has ceased. They should, therefore, invariably be treated by the application of a support fitted to the corrected position of the spine, worn night and day, and only removed half an hour daily for exercise and massage. This support must only be omitted when the spine remains quite straight when it is removed.

In the upper limb curvatures of the humerus and of the radius are occasionally produced by crawling. They practically never arise whilst the child is under treatment, so that nothing can be done to prevent them. Nor do they call for corrective treatment.

The most frequent deformities of the lower limbs, bowing outwards and forwards of the femur and tibia, arise before the child has learned to walk; they are due to the cross-legged sitting posture, and not to standing. The erect position may tend to increase them so long as the bones are soft, but such increase as will occur in the course of three months is slight, and it is now very generally agreed that it is better not to apply splints to prevent walking. The loss of the natural muscular action and the pressure of the bandages is likely to affect the nutrition of the limbs, and in the opinion of many, the harm thus done more than counterbalances the benefit derived.

Knock-knee differs in that the mechanical factor in its production is the weight of the body in the erect position, that the deformity may tend to increase after the active disease has ceased, and that the strain thrown upon the knee-joints tends to stretch the ligaments and produce lateral mobility of the joint. Although again it is not advisable to prevent the use of the limbs altogether, some support is necessary, particularly in older children. This should take the form of an outside splint or steel brace fitted below into the boot, the knee being drawn outwards by a knee-cap. The child is thus enabled to walk with a stiff knee.

Treated by such expectant measures with the addition of external support in case of the spine and of knock-knee, rickety deformities in young children tend to improve. Surgical treatment for the purpose of correction is usually unnecessary. Operation should not be advised before the age of four years unless the deformity is of exceptional severity, after the age of four it is well to correct the deformities unless they are slight or are improving rapidly. Curvatures of the tibia are best corrected by osteoclasis, a greenstick fracture being produced which unites rapidly and gives an æsthetic result which is more perfect than that yielded by osteotomy. Genu Valgum in its slighter degrees can be corrected by means of a rack splint in the course of four to six weeks, an outside brace being applied for a few months afterwards. If more severe in degree, Genu Valgum calls for an osteotomy of the femur (McEwen). Other deformities such as bowing of the femur, only very occasionally require correction by operation.

Continued, recrudescent and adolescent rickets, require the same methods of treatment as does the disease when it occurs in infancy. The diet must be modified to suit the age of the child, but the principle of increasing the proportion of fat and proteins, and diminishing the carbohydrates is the same. As already mentioned, some cases of continued rickets are extremely difficult to cure by dieting and hygienic measures, and in them the evidences of active disease may persist for years. In such cases the deformities tend to progress, and the application of braces is more often necessary. Occasionally in these cases the question will arise as to the expediency of operation for the correction of deformity whilst the disease is still active. In general it may be said that operative treatment is better postponed, but the correction of the deformities by rack splints or braces may be carried out. Very occasionally, when a deformity such as knock-knee is so severe in degree as to prevent walking, it may, however, be desirable to operate in spite of the fact that the disease is active in order that the limb may be brought into use, and a certain amount of exercise taken. R. C. E.

SCURVY, INCLUDING INFANTILE SCURVY

In spite of the divergent views which are held concerning the causation of scurvy, there is a consensus of opinion as to the methods by which it may be prevented and cured.

In 1795 Sir Gilbert Blane obtained the

introduction of lime juice into the British Navy, a measure which was promptly followed by a decrease in the incidence and severity of the disease, quickly converting it from the most terrible scourge to a condition of little moment. The success which has attended anti-scorbutic treatment may be gauged by the following figures: For the twelve years following 1851, 1058 cases were admitted to the Dreadnought Hospital Ship lying off Greenwich. Between 1899 and 1909 ten cases only were reported by Dr. Herbert Williams of the Port of London Sanitary Committee.

The treatment of scurvy is based on the knowledge that there is in fresh vegetables, fruits and animal fluids such as milk and blood, something which is absent in the same substances when dried, and which is capable of preventing scurvy. What this "anti-scorbutic element" actually is, has not been determined. It is present in greatest abundance in fresh green vegetables such as cabbage, lettuce and cress, and in yams, onions and potatoes; fresh fruits, such as limes, oranges, lemons and apples, are rich in it; preserved vegetables and fruits contain it to a less degree. It has been supposed that the organic acids present in certain vegetables and fruits constitute the anti-scorbutic element, but citric and tartaric acids, if administered alone, are of little or no value; the former is not permitted on British ships. Moreover, these acids are not present in some well-recognised anti-scorbutic foods, such as the potato. Sir Alfred Garrod held the view that potassium was deficient in the diet of those who developed scurvy, but there is no constant proportion between the value of a food as an anti-scorbutic and its potassium content. Sir Almroth Wright regards scurvy as an acid-intoxication induced by an absence or deficiency of alkaline foodstuffs, or an excess of acid-containing foods. He divides foods for this purpose into those which, on incineration, leave behind an acid ash, such as meats and cereals; those leaving a neutral ash; and those leaving an alkaline ash, such as roots, tubers, fruits and fruit juices, the blood of animals and milk. It is well known that a diet consisting exclusively of the first group induces scurvy, which may be cured by the administration of the members of the last. Against this view is the fact that scurvy does not resemble closely the condition which may be caused in animals by poisoning with acids. The work of Hölst and Fröhlich makes such a view untenable. These workers have shown that rabbits fed on a scurvy-producing diet (cereals) can only be kept free from scurvy if *fresh* vegetable food is given, and not if the vegetable is dried previously, even if large quantities of sodium bicarbonate be added to it. There is little to support the view that tainted meat is chiefly responsible for scurvy, for it has occurred in children who are breast-fed or fed on sterilised milk; moreover, the signs of ptomaine poisoning are wanting. The opinion that it is infective in origin has little influence on treatment. A rapid transmission of the disease from one community to another has been reported by Dr. Myers Coplans, but it has been contended with reason that the condition which he described was not scurvy but an epidemic form of stomatitis.

Recent work promises to lead to a more scientific and accurate knowledge of the hitherto intangible "anti-scorbutic element." Thus Funk has isolated from various living structures substances to which he has given the name "vitamines." He considers it essential that these should be present in the food if proper growth and development are to be maintained. It is important in connection with the subject of scurvy that he has demonstrated the presence of vitamines in fresh milk, and in many of the anti-scorbutic foods, and more especially that he has isolated them in appreciable amounts from lime juice. According to this observer, vitamines are soluble in water, dialysable, and destroyed by heating to 130° C. They are isolated in a crystalline form and are neither salts nor proteins. Schaumann states that such substances are probably very numerous and at present mostly unknown. They probably seldom exist in the free state, but are constituents of more complicated molecules such as nucleins and phosphatids. Among the diseases which their absence in food produces are scurvy and infantile scurvy. F. Gowland Hopkins in order to study these substances has conducted feeding experiments on a large scale in rats. He has shown that on an artificial diet containing pure proteins, fats, carbohydrates and salts in correct proportions, young rats ceased to grow in about fifteen days, though the addition of a minute quantity of certain tissue extracts and fractions of such extracts secured normal growth. He thinks that little can be said at present as to their chemical nature, but is of opinion that as growth is arrested when these bodies are absent from the dietary, it is reasonable to suppose that diseases of nutrition, such as scurvy, may be produced in like manner.

From what has been said it is clear that prophylactic measures are of the first importance. Ships should carry a supply of preserved vegetables and fruits, and some anti-scorbutic preparation such as lime juice. In this respect short voyages are attended with less risk from scurvy than long ones. Even under the modern improved methods of preservation, fresh vegetables and fruits are more anti-scorbutic than

those which are preserved, so every opportunity should be taken of procuring fresh vegetables when the vessel touches port. Too absolute a reliance should not be placed upon lime juice, for if taken regularly it is apt to become distasteful and may set up digestive or intestinal disorders. For this reason it is difficult to be sure that it is being taken except under conditions of discipline, as in the Royal Navy. The same difficulty to a greater extent underlies the suggestion of Sir Almroth Wright, who recommends the administration of such essential anti-scorbutics as sodium lactate, calcium chloride or Rochelle salt instead of lime juice.

Contributing factors which make for freedom from scurvy are the maintenance of good general health, warm clothing, efficient ventilation and moderate exercise. Good nutritious food, including fresh or well-preserved meat, may be counted among the preventive measures, apart from any specific anti-scorbutic element which they contain.

When the disease is actually present, it yields readily to treatment if the proper remedies are procurable, and in two or three weeks all but the severest cases will end successfully. Generally a diet including green vegetables and fresh fruits is all that is necessary, care being taken that these are not pushed to excess, so that they do not disturb digestion, produce diarrhœa or renew a former dysentery. Lime juice, orange juice or lemon juice are only needed if fresh vegetables or fruits cannot be obtained. Effusions into the pleural or peritoneal cavities may require aspiration if they are bulky or persistent. Absorption of the extravasations under the periosteum may be accelerated by gentle massage if they prove obstinate. In severe cases local treatment may be necessary for the gums, to stop the oozing and assist their hardening and shrinking. An antiseptic and deodorant mouth-wash such as sanitas or Condy's fluid, aided by the application of solid caustic potash or sulphate of copper, fulfils these requirements. If hæmorrhagic ulcers are present they may be bathed with mild antiseptic lotions or normal saline, and should be dressed aseptically in the usual way. During convalescence iron preparations are indicated to treat the anæmia, which is often profound.

Infantile Scurvy

The treatment of scurvy in infants is based on the same principles as in adults. The anti-scorbutic element, however, has to be supplied in diet of a fluid or semi-solid nature. The first essential point is to stop the particular diet which has led to the production of the disease. This is usually some form of proprietary food, especially one which is dessicated or prepared from cereals. Dr. Edmund Cautley gives the diet in 553 collected cases: Proprietary foods 250, sterilised milk 122, pasteurised milk 40, boiled milk 14, humanised milk 6, uncooked cows' milk 5, condensed milk 72, dried milk foods and water only 21, breast milk and additional food 2, breast milk alone 21. As he remarks, "obviously the diet most likely to cause the disease is the one farthest removed in character from human milk, and from fresh, as opposed to cooked, food." If it be considered advisable to feed an infant on a proprietary food or a milk which has been sterilised or subjected to laboratory manipulation, chemical or physical, about a teaspoonful of fresh fruit juice should be given two or three times weekly to minimise the risk of producing scurvy. In all but exceptional cases such forms of food are better avoided.

The scurvy-producing food having been replaced by good fresh milk, the condition will gradually improve in the majority of cases until recovery is complete. The duration of the disease will be shortened by giving fresh fruit juices such as those of oranges, lemons, apples and grapes, sweetened. Potato cream, as recommended by the late Dr. Cheadle, is a valuable remedy. It is made thus: the potato is baked in its skin, the floury part under the skin is scraped off and mixed with milk, in the proportion of a teaspoonful of the potato to an ounce of milk. One to two teaspoonfuls may be given three or four times a day. It is not suitable for infants under seven months old. Raw meat juice, although not a very powerful anti-scorbutic, is useful because it also combats the anæmia. Vegetable soups and purées may be given to children of ten months old and upwards. If the milk is digested with difficulty it may be citrated by adding citrate of soda in the proportion of 2 gr. to the ounce of milk. Sodium lactate or bicarbonate may be used to counteract the diminution of the alkalinity of the blood, which Sir Almroth Wright has shown to be present. In this way it probably lessens the tendency to hæmorrhage.

Very careful nursing is required in cases of infantile scurvy, for the limbs are often so tender that the baby cries out in alarm as one approaches the cot. The weight of the bedclothes should be taken off by means of a cradle, and the tender limbs should be kept at rest by sand bags. If orbital hæmorrhage produces proptosis, the conjunctival sac should be kept bathed with 4 per cent. solution of boracic acid. The gums may be swabbed gently with a mixture of equal parts of lemon and glycerine, or equal parts of glycerinum boracis and glycerinum potassii chloratis. Occasionally the periosteal hæmorrhages are very slow to disappear when the disease is

otherwise over. At this stage, tenderness being no longer present, very gentle massage may be employed to promote their absorption. The anæmia may be treated by raw meat juice, as mentioned above, or by the administration of iron. F. S. L.

TREATMENT OF DISEASES OF THE RESPIRATORY SYSTEM

VACCINE TREATMENT OF DISEASES OF THE UPPER AIR-PASSAGES

It is not within the scope of this article to give an account of work done elsewhere on vaccine treatment of diseases of the upper air-passages. The following description is the result of my personal experience of vaccines made for my patients by Dr. M. H. Gordon of St. Bartholomew's Hospital, during the last seven years.

Great care has been observed in the selection of the patients, and no treatment has been undertaken without repeated examinations. The methods employed consist of—

1. **The Collection of Secretion.**—When taking a specimen from the nose, the vestibule must be carefully cleansed to prevent contamination by superficial organisms. The secretion is then obtained by a platinum loop, forceps, or a swab of sterilised wool wrapped round a probe. In the case of an accessory sinus the nose is first syringed with normal saline solution, and a weak cocaine and adrenalin mixture is applied to the opening of the suspected sinus, so that the discharge shall escape more easily. If this fails, the secretion is aspirated through a canula, or an exploring needle is inserted into the sinus and the discharge expelled into a sterilised bowl by the injection of air or normal saline solution. For rough examinations it is sufficient if the patient blows his nose into sterile gauze. Whenever possible the secretion should be examined at once. Where this is impossible it should be placed in a closed bottle or tube containing sterilised saline solution, to prevent it from drying. Secretion is obtained from the naso-pharynx by suitable forceps or swabs, the tongue being depressed by a spatula, so that the mouth organisms are excluded. An excellent instrument has been devised by C. E. West for this purpose. It consists of a silver tube with a curved end through which runs a wire carrying a swab; the whole appliance can be easily sterilised. When passed into the naso-pharynx or larynx, the swab is pushed out and withdrawn again within the tube before removal of the instrument. Post-nasal secretion or sputum may be obtained by spitting, if the mouth is first cleansed by repeated gargling with sterile water.

2. **Examination of Secretions.** (a) *By Films.*—These are stained by ordinary methods, especially Gram-fuchsin, to determine what organisms are present and to gain a rough idea of their nature and relative number. Such examinations are most important to show whether proper care has been taken in collecting the secretion, whether the organisms persist in the same number at different stages of treatment, and whether there is evidence of phagocytosis.

(b) *By Cultures.*—Whenever possible the collected secretion is smeared at once on blood-agar tubes or plates and incubated at a temperature of 37° C. for twenty-four hours or longer, the various organisms requiring different periods for their growth. The culture must be examined at the end of this interval to determine the principal organisms. The fact that some of these grow more readily than others is important. The prevalent infection must be determined by the number and not by the size of the colonies which have grown, and by comparing the cultures with films made from the secretion. Pure cultures are very rare, but in many instances one type of organism is prevalent, especially influenza or streptococcus. These two are the commonest persistent infections of the nose. The culture more generally found is a mixed one, and in most cases only two organisms are prevalent. In many instances the same combination persists for long periods to the exclusion of everything else. This is found even with relapsing infections such as colds. To make certain of the exact nature of an infection the examinations must be repeated, and, in order that mistakes may be avoided, vaccine treatment should never be begun until this has been done.

Mixed cultures with more than two organisms prevalent are also common in infections of the lower air-passages.

Sterile cultures are almost unknown, with the exception of chronic influenza infections; these are extremely difficult to cultivate, and likely, therefore, to be overlooked.

Contaminations from the mouth, vestibule, skin and air are difficult to avoid, and it is essential that the clinician should consult with his bacteriologist regarding the symptoms of every case. Our observations on these lines have convinced us that it is often possible to say beforehand what the infection is likely to be.

Blood cultures and serum diagnosis may be of great value especially in acute infections. The Opsonic Index is not often of practical value.

3. **Vaccines, Non-sensitised.** (In most of my cases autogenous vaccines have been used in preference to stock preparations.)—The bacteria may be killed by heat or by the action of some chemical agent such as concentrated galactose, ether or phenol. Another method consists in incubating the suspension of bacteria in saline solution or distilled water at 37° C., the result being that after a short time the organisms are killed and undergo autolysis. The vaccine may be put up in sealed glass capsules, each containing a known number of organisms suspended in normal saline solution (1 per cent.) and phenol (0·5 per cent.).

4. **Dosage.**—There is evidence to show that after an injection of vaccine there is a definite period during which the quantity of anti-bodies circulating in the blood is decreased. This is called the "negative phase," and may last for a few hours or for many days. The degree of the reaction depends on the size and virulence of the dose and the resistance of the patient. As a rule, in twenty-four hours the patient passes into the so-called "positive phase," the duration of which is variable.

It has been found that some people were very susceptible, and that reactions, both local and general, were much more frequent than is generally supposed. When treating diseases of the upper air-passages, therefore, one must be careful of the so-called negative phase. The following is a rough guide to doses—

With influenza, streptococcus, pneumococcus, coliform, diphtheria group and coryza the primary dose of vaccine should be 1 to 5 millions; with Friedlander and catarrhalis 5 to 10 millions; with staphylococcus 10 to 25 millions.

The doses should be increased gradually if the first reaction is not too marked. At least six to eight injections should be given at regular intervals of about a week. To get a patient rapidly under the influence of vaccine, increasing doses are given on three succeeding days (Fornet and Müller). This is a safe method when starting treatment, as it is possible to inject a small first dose and then to increase it if no reaction is obtained. With smaller doses, shorter intervals than a week are required. In many instances it is necessary to continue treatment for long periods with gradually increasing intervals, because the duration of immunity varies greatly with different patients. For instance, one person may be cured of colds with a few doses and remain immune for years; another may need treatment to be repeated every winter; rarely, a good result is obtained after a long course lasting one to two years.

I have made it a general rule to continue a vaccine treatment for so long as I was convinced that the patient was better, but a word of caution is necessary. After a course of vaccines, whether the patient is better or not, the secretion should be re-examined, because there is sometimes a definite change in the infection, and in this case it is necessary to make the vaccine correspond. There seems little doubt that some organisms are more difficult to dislodge than others, *e. g.* influenza, which is more persistent than catarrhalis.

The injections should be made into the subcutaneous tissues of the outer side of the forearm or the back of the arm above the elbow. In women the back of the shoulder or the lateral side of the thigh may be preferred. Care should be taken that the syringe is sterile and that the injection avoids the main cutaneous nerves.

[For details concerning sensitised vaccines, see article on *Vaccine and Serum Therapy*.]

General Considerations

Reaction. *At Site of Injection.*—Slight swelling and redness and, later, tenderness and stiffness of the parts injected are the normal conditions after vaccination. These signs usually disappear after forty-eight hours. It is by no means uncommon, however, for local reactions to be more severe, and acute inflammation may be caused and last for several days. Rarely, an abscess forms but only after sensitised vaccines.

Local Condition.—Patients often complain that their symptoms are worse. Thus in cases of sinusitis the discharge may be definitely increased for a short time. It has been said that a sharp reaction of this kind is a favourable sign, but there is little evidence to prove it.

General Condition.—Lassitude, slackness, and a slight degree of malaise often follow within twelve hours of injection. The next day there may be a feeling of exhilaration, which tends to make the patient confident of success. In many people vaccines serve as a general tonic. I have found that a small dose of staphylococcus makes one energetic for several days. The same result is not obtained by injecting saline.

Dangers.—What is the danger of vaccines? The question is asked repeatedly by doctors as well as patients. Most of us have a natural dislike for germs; a few people obstinately refuse to have them injected.

Vaccines have been accused of causing disastrous results, but the cases are difficult to find. Doubtless there is real danger, especially in acute diseases. I feel convinced that we do not yet know to what extent and to what

lengths it is safe to give this treatment. I am always nervous about sending vaccines to a general practitioner who has no experience. I must confess that I have seen no case which was permanently worse after inoculation, but slight difficulties and complications are often met with. Even then it is hard to decide how much is *propter hoc* rather than *post hoc.*

It has been found that lassitude, faintness, nausea, and colds in the head are fairly common results. Epistaxis is occasionally caused, but anything else is rare. Instances have occurred of high temperature (4 cases), mental depression (common in slight forms), inflammation of glands (2 cases), of ears (2 cases of middle-ear suppuration forty-eight hours after vaccine), of joints (1 case), of skin (especially a return of some old skin eruption such as urticaria), of nerves (2 cases of severe neuritis), of eyes (1 case of recurrent iritis), of abdominal inflammation (*e. g.* return of gastritis or colitis), of jaundice (1 case), which were probably due to vaccines. There have been very few instances of later complications, but two cases had a return of their phthisis, one suffered from erysipelas, one from carbuncle, and one from double pneumonia, within three months of treatment.

Failures.—Doubtless a fair proportion of failures is due to our ignorance about the whole question. There is still much to be learnt about the causes of air-passage infections, and it is to be hoped that vaccines will help in the solution of the problems. Until more is known it is impossible to avoid giving wrong vaccines and wrong doses. It is often difficult to determine how long the treatment should be continued, and many people have neither the confidence nor the patience to persevere. It is now known that similar vaccines may have different curative values; and, apart from such considerations, it must be remembered that in diseases of the upper air-passages the organisms concerned are chiefly situated in the secretions on the surface of the membranes, and are, therefore, to some extent removed from the immediate action of the blood and lymph.

Results that can be Obtained with Vaccines.—To determine what results can be obtained with vaccines it is essential to approach the question from at least two standpoints. We want to know first whether better results can be obtained with some diseases than others, and secondly, whether vaccines of different types give variable results. If these differences can be proved it will help to solve our difficulties. Unfortunately our bacteriologists are too enthusiastic, and there are some people who seem totally unable to distinguish whether their patients are better or worse. The patients often expect too much, and say they are better, although the local condition is unchanged. It is natural to think of faith-healing, and doubtless a vaccine is as good in this respect as a bottle of medicine. Personally, I believe that vaccines have definite curative value in some affections of the upper air-passages; that as a general rule they are more successful in cases with intermittent periods of good health than with persistent infections such as chronic sinusitis or bronchitis where gross changes have taken place in the mucous membranes; and that with them it is easier to improve the general health than the local condition of the patient.

Acute Septic Infections.—To obtain a successful result in an acute septic infection large doses should be given early and repeated as quickly as possible. I believe that these requirements can be met better since the introduction of sensitised vaccines, because the latter are less likely than non-sensitised preparations to make the patient worse.

Of three cases treated with killed sensitised vaccines in my department at St. Bartholomew's Hospital by Gordon, one was that of a man who had submitted to an operation on his septum and tonsils. Seven days later he had acute middle-ear suppuration and his drums were punctured. On the ninth day my colleague Scott performed a Schwartze operation on his mastoid, which was found to contain a pure streptococcus infection. On the eleventh day he appeared generally septic with signs of early meningitis. We were both afraid that he would die. The next day he seemed worse and 50 millions of sensitised streptococci were injected. Within a few hours he was definitely better, and sat up and ate his food. One hundred and 500 millions were given on the next two days. On the fourteenth day he was practically well. His temperature chart showed a drop of one degree after each injection, a result also observed by Gordon in other cases. There seemed little doubt that the vaccine had saved the patient's life.

Shortly afterwards one of our house-surgeons was ill with acute inflammation of the tonsils and pharynx. The infection was very severe and was followed by cellulitis of the neck and laryngeal obstruction. On the third day his neck was incised and tracheotomy and further incisions were necessary four days after. Sensitised streptococcus vaccines (50, 100, 500 millions) were given on the fifth, sixth, and seventh days. The temperature gradually fell and was normal seven days later. The tracheotomy tube was removed on the twelfth day. Although this case is not so convincing as the former, the recovery was very good, and probably the vaccine helped.

A third case, under my colleague West, had a radical mastoid operation with drainage of

extra-dural abscess. Four days later the transverse sinus was explored, but was not thrombosed. The next day the cerebellum was explored, but no abscess found. Three days later streptococci were present in the blood, and he was given sensitised vaccines in doses of 50, 100, and 500 millions. The next day temperature was normal, and rapid recovery ensued.

In this connection it should be stated that West has treated two other ear cases, both suffering from transverse sinus thrombosis and desperately ill, with anti-streptococcic serum and sensitised vaccine, with no effect. Both patients died. It is yet too early, therefore, to say how much these inoculations will help us in the treatment of acute infections of the upper respiratory tract.

"Colds." Rhinitis, Pharyngitis, Laryngitis, Tracheitis, Bronchitis

1. **Acute Infection.**—I have treated a large number of these infections in the last four years, the majority with catarrhalis, pneumococcus, or influenza vaccines, or combinations of these. Coryza cases have not been so common, and other organisms have been rare.

The vaccine should be given early, if possible within the first twenty-four hours. By injecting myself with a single dose (5 millions each) of catarrhalis, pneumococcus, and influenza vaccines, as soon as the severe symptoms commenced, I have succeeded in curing my last three bad colds, and the attacks have been completely relieved in twenty-four hours. From the second day onwards vaccines must be used with great caution; after the sixth day they are less likely to upset the patient, and cases of copious discharge of ten days' duration can sometimes be cured rapidly by small doses on two or three successive days. It should be a rule never to give a large dose to a patient with a severe cold.

During recent years there have been epidemics of severe colds followed by irritating cough and expectoration lasting for several months. Such colds have affected adults as well as children, and have caused many a sleepless night. Sickness has been a common symptom in children, and asthmatic attacks in men. Pneumococcus and catarrhalis have been the prevalent organisms. Such cases do well with vaccines, but everything else has failed.

There seems to be abundant evidence that vaccines will often cure a cold, and the question naturally arises whether they should be used for preventive inoculation. When it is known that a severe epidemic, say of influenza, is prevalent in a town, and the facts have been proved by bacteriological examinations, the general practitioner should have his stock ready, and, as soon as one case is affected, he should not hesitate to inoculate the rest of the household. Some of his patients will be protected, others may have the disease slightly—none of them will be any worse.

2. **Chronic Infections.**—Vaccines have also been given to many of my patients suffering from severe intermittent infections of their upper air-passages. Such cases are common and present a remarkable similarity in their histories. The patients complain of having had colds for many years or all their life; that their attacks last for weeks and recur at frequent intervals; that they get their colds regardless of exposure, more frequently in the winter; that they know when a fresh attack is coming because of unpleasant sensations; many of them are slightly feverish in the early stages of each attack, and some of them are suspected of tuberculosis. The fact that sinusitis never occurs in this group is of great importance and difficult to explain.

It has been found that in many of these cases the prevalent infection was influenza, pneumococcus, or catarrhalis; that coryza is very rare; that Friedlander's bacillus, diphtheroids, streptococci, and staphylococci are of little practical importance; that it is the rule for the same organisms to reappear with each succeeding cold; in other words, that they are very persistent. That the majority of cases fall into two main groups: (*a*) influenza, commonly combined with pneumococcus; (*b*) pneumococcus and catarrhalis, constantly found together. That vaccines have a definite curative value and give markedly better results than are obtained with cases of sinusitis, presumably because of the intermittent periods of normal health which occur in the former class.

Thus, of fourteen cases with influenza infections, definite improvement was noted in eight; and still better results were obtained in the pneumococcus and catarrhalis group, eleven out of fifteen receiving benefit. That the sense of smell and taste may return even in cases which have had none for many years. That a fair proportion of the patients were highly susceptible to vaccines and were unable to tolerate the ordinary doses.

Post-Nasal Catarrh and Deafness.—My experience of vaccines in post-nasal catarrh and deafness has been limited, but my impression is that it is easier to improve the catarrh than the deafness. Very rarely a patient will say that he has heard better for a time. West states that: "Friedlander infections seem to do well, and catarrhalis quickly disappears . . . staphylococcus aureus seems to be a

favourable case for vaccination, and streptococci certainly diminish or disappear in some cases. On the other hand, the pneumococcus has so far defied my efforts . . ."

Asthma and Hay Fever.—It is not within the scope of this paper to enter into a discussion on the results that can be obtained by vaccination in cases of asthma and hay fever. My experience is limited to those cases which were associated with infections of the upper air-passages, and it has been found that when the rhinitis and bronchitis improved with vaccines the asthma and hay fever were less severe. There seems to be conclusive evidence that inoculations will in some instances protect a patient from asthmatic attacks, and the same is true to a less extent with the secondary infections of hay fever.

Furunculosis.—Four cases of furunculosis affecting the vestibule of the nose, and skin of nose and face, have been treated with staphylococcus vaccines and all improved.

Glands in Neck.—In 1911 a patient was sent to me with numerous glands in the neck which on section appeared to be lymphadenoma. He was found to have a muco-purulent discharge in his nose and the prevalent organism was staphylococcus aureus. A vaccine was prepared and given in doses of 10 to 200 millions by Dr. C. R. Stewart, who reported in June 1913 that "the vaccines undoubtedly relieved to a great extent the rhinitis, which was thought possibly to account for the enlarged glands. The patient also had a course of X-rays and the glands have gone down markedly but return at times."

Sinusitis, Acute.—A few cases of acute sinusitis have been treated with vaccines of streptococcus, influenza, or pneumococcus. Since most of these cases recover quickly, if treated early by a specialist, it is difficult to determine the exact value of inoculations. I believe, however, that streptococcus and pneumococcus infections can often be cured more quickly by vaccination than any other method, and I have no doubt that sensitised vaccines are of great value because it is possible to give a succession of large doses in a short period without affecting the general health. Influenza vaccines, on the other hand, are very depressing. They should be used cautiously and in small doses on three successive days. With this method rapid improvement has been obtained with them.

Sinusitis, Chronic.—A large number of cases of chronic sinusitis have been treated with vaccines for varying periods. In most instances there was a long history of suppuration, and other treatment such as operations had failed to cure. These persistent discharges were more often due to infections with influenza, streptococcus, and Friedlander's bacillus, than other organisms. The same organism was often prevalent in each case for long periods. Mixed infections were more common than pure. In many of these only two organisms were prevalent at one time. In some instances the combination changed. Influenza and pneumococcus were more persistent than any other combination.

Mixed infections with more than two organisms present in quantity were not often selected for treatment because the bacteriology varied with different examinations, and it was difficult to determine the exact nature of the infection.

Cases with stinking discharge in the maxillary sinus were never inoculated because they invariably did well with operations.

Catarrhalis and coryza were considered of little clinical importance because they rarely persisted long enough to require vaccines.

I have had little experience of other organisms such as diphtheroids apart from atrophic rhinitis.

I have made it a rule to use vaccines containing as few strains as possible with the idea of ascertaining whether better results can be obtained with some vaccines than others. My conclusions are as follows—

Streptococcus vaccines gave fair results. Six of nine cases were definitely improved. The same is true of Friedlander vaccines, as three out of six did well.

Of pneumococcus vaccines it is rather difficult to speak. Two patients out of six recovered, but both had recent infections. The cases with long histories were not improved at any time. It seems possible that better results may be expected by treatment with sensitised strains.

Influenza vaccines were useless. Eleven cases were treated and no good result was obtained. Such infections are most difficult to cure with any treatment; operations are rarely successful. I regard the influenza bacillus as the worst and most persistent infection of the nasal sinuses.

Staphylococcus and coliform vaccines (two cases each) were valueless, but all four patients had poor general health and very advanced disease in their sinuses. Lastly, of five cases treated with mixed vaccines three seemed less susceptible to colds.

It appears, therefore, that chronic sinusitis can rarely be cured by vaccines. I am unable to explain why better results were obtained with streptococcus and Friedlander's bacillus than with other organisms. Possibly these infections are less persistent.

A remarkable effect is sometimes obtained with sensitised streptococcus vaccines. A patient came to my hospital with purulent discharge

from her antra and fronto-ethmoidal cells of many years' duration. Her antra were drained, but the discharge did not improve. She was then given vaccine, and forty-eight hours after the second dose (25 millions) the discharge completely ceased in the left nasal fossa. A third dose of 100 millions was injected in due course, and seven days later it was found that the suppuration in the right side had almost disappeared. She remained well for three months and then went to Canada.

A second case had had repeated operations on the septum and nasal sinuses. During the past year she had used thirty to forty handkerchiefs regularly every week. She had headaches and very poor health. She was suffering from a streptococcus infection of all the sinuses. After the second dose of sensitised streptococcus her discharge was suddenly reduced so that she only required one handkerchief a day. Her headaches were slightly better and the improvement lasted for nine weeks. She did not return, however, for two months, when four more doses were given with no effect. Six months later the same infection was present and the vaccine was tried again. After the second dose the discharge immediately lessened and once more her health improved. This patient is still under treatment.

There have been no other cases in which a similar result was obtained, but one cannot fail to be impressed by the effects produced in these two instances. Moreover, we have had several cases of acute streptococcic tonsilitis which were cured rapidly by sensitised vaccines. These patients stated that they felt better within a few hours of injection and their pain and temperature improved almost at once.

I must again draw attention to the great susceptibility of these patients, especially to influenza vaccines, which are often depressing. It is easy to exacerbate the discharge with large doses, and there is no evidence to show that marked reactions are followed by a corresponding improvement in the sinusitis. On the other hand I know of no case which was made permanently worse by inoculations.

Atrophic Rhinitis.—The true cause of this disease must still be regarded as doubtful. In a series of fourteen cases the most prevalent organism was a Friedlander bacillus which was found in every case, and which grew with such ease and rapidity that other forms were overshadowed. Influenza was present in five cases, pseudo-diphtheria in four, streptococci in two, and staphylococcus aureus in only one. Almost without exception the infections appeared to be mixed and two or more organisms grew freely with each examination.

The results of inoculation with the different autogenous vaccines have been completely unsatisfactory in spite of the fact that doses from 10–1000 millions were employed and treatment was continued in some cases for many months. In only two was there any real improvement in local conditions, and this was probably due to other treatment given at the same time. In most cases treatment was not continued for long periods, because there was no sign of any improvement, and eight of the patients were distinctly upset and complained of various symptoms including lassitude, colds in the head, exaggeration of headaches, faintness, sickness, and abdominal pains. It is interesting to note that gastritis or colitis was complained of by several patients, and one of the series refused to continue the treatment because it made her colitis worse. When Friedlander vaccine has been used for other conditions it has not caused similar toxic troubles. Although the series is not a large one, there has been nothing to make one believe that this vaccine has any curative value in atrophic rhinitis. Recently, a new organism has been discovered, namely the bacillus of Perez, which is supposed to be the cause of this disease. Vaccines of this bacillus have been tried in different countries and good results have been claimed.

Vaccines before Operations

When an operation on the upper air-passages is followed by general septic infection of the blood or by cerebral complications the result is due in most instances to streptococcus or pneumococcus invasion. It occurred to me, therefore, that attempts ought to be made to immunise my patients before undertaking serious operations upon them.

In this connection it is now generally recognised that many animals can be protected against infections of various kinds by protective vaccination, and I decided to make experiments to see whether similar results could be obtained in men. One of my first patients was a man who had eight operations in India for a persistent suppuration of the frontal sinuses. I performed a Killian operation on the right frontal sinus, and gave 50 millions streptococcus vaccine twenty-four hours later. His wound healed slowly, and the temperature remained above normal for ten days. Six weeks later a similar operation was performed on the left side, but a dose of 100 millions had been given twenty-four hours before. This wound healed rapidly and the temperature was hardly raised. The after history is interesting; on the left side the result was excellent, but the right did not do well. The discharge persisted, and the patient complained of headaches from time to time. The case impressed me so much that I determined to make further investigations, and

shortly afterwards another case came to me suffering from streptococcus infection of the frontal and antral cells. This patient was carefully prepared by vaccines previous to his Killian operation. The result was most successful, and there was rapid cessation of discharge. Since then I have made it a rule to give vaccine or serum to any patient before undertaking a major operation. Of five patients with malignant growths in the jaw or larynx, four have done uncommonly well; the fifth, a case of carcinoma of the larynx, had a septic wound and secondary hæmorrhage eight days after operation, but ultimately made a recovery.

It remains to be seen, therefore, whether it is possible to immunise a patient temporarily, and so avoid the high temperature, septic wounds, periostitis, septic discharge, and cerebral complications which are so dangerous in these cases.

In conclusion, my impression is that we have already reached a point at which it is safe to say that vaccines have a definite curative value in some infections of the upper air-passages. The subject is intensely complicated, and there is no doubt that it must receive a great deal more attention before vaccines will be of great practical value to the practitioner.

W. D. H.

DISEASES OF THE BRONCHI

Bronchitis or catarrhal inflammation of the bronchial mucosa is a common affection; it may be divided into acute and chronic forms, the division being important, in so far as the treatment of the two conditions is, in some respects, different. The bronchial mucosa is in direct communication with that lining the nose, naso-pharynx and pharynx, and any infective process present in these cavities is liable, under favourable conditions for their development, to spread to the bronchial tubes. Furthermore, varying blood states and circulatory disturbances in the lungs are apt to favour inflammation of the bronchial mucosa.

Among the causes of acute bronchitis, the commonest is a simple extension of an ordinary coryza into the bronchial tubes, occurring in association with exposure to rapid changes of temperature. It occurs also as an accompaniment of certain specific diseases, such as measles, whooping-cough, typhoid, malaria and certain diseases of the lung, such as pneumonia. It may, or may not, be present as part of an asthmatic attack. The inhalation of irritating particles or gases may induce it. These so-called causes are to be regarded as predisposing only, the real causative factor being some infecting micro-organism.

Chronic bronchitis is most frequently met with in association with chronic affections of the lung, such as emphysema, chronic pulmonary tuberculosis, fibroid disease; affections of the heart, especially disease of the mitral valve, and of the vessels, such as general arterio-sclerosis in association with acute and chronic renal disease. Any local disease of the lung, such as pressure from an aneurysm or growth, will induce a condition of chronic bronchitis in its neighbourhood. Over-indulgence in food and alcohol is a common cause of chronic bronchitis. Certain drugs, such as iodine and bromine, are excreted by the bronchial mucosa, and in the process of excretion induce some degree of bronchial inflammation.

The close association between attacks of bronchitis and the presence of infecting organisms is plainly shown by the immunity from this disease those who live in clean and often very cold atmospheres enjoy, such as Arctic explorers. On their return to a warm, germ-laden atmosphere they usually suffer from severe attacks of bronchial catarrh.

As in the rational treatment of any morbid process it is of the utmost importance that the primary cause of the condition should be recognised, so that although we may in a case of acute bronchitis be reduced to treating the symptoms only (and indeed this is all that is usually necessary), the importance of the presence of the infecting organism must never be lost sight of, and where possible, cultures of the bronchial secretion should always be taken. The more common organisms found in association with this condition are the pneumococcus, Friedländer bacillus, streptococcus, Micrococcus catarrhalis and the influenza bacillus. The typhoid bacillus is found where the bronchitis occurs in the early days of typhoid fever.

During an attack of *acute bronchitis,* the patient's room should be maintained at a temperature of about 65° F. The air should be moist but not super-saturated. Indeed, the great use of the oft-seen steam kettle is in warming the air rather than in moistening it. It is conceivable that the steam kettle as often used is more damaging than advantageous, infants and those with weak expiratory power being drowned in their own secretions. The steam when used may be medicated with aromatics such as compound tincture of benzoin or eucalyptus. If the cough is very dry, and the secretion tenacious, the steam kettle may be used with advantage, but it should be withheld directly the secretion becomes loose. In severe cases the patient should be confined to bed and the bowels should be well opened with a brisk saline purge. A diaphoretic should be given, and in robust individuals this may be combined with small

doses of antimony in a prescription such as the following—

> ℞ Vini Antimonialis ♏ vii
> Spiritus Ætheris Nitrosi ♏ xx
> Liquor Ammon. Acetatis ʒ ii
> Syrup. Tolutani ʒ i
> Aquam Camphoræ ad ℥ i

This dose to be given every four hours.

Sweating can be increased by placing the patient in a hot pack. Plenty of fluid should be taken. Alcohol should not be prescribed unless the patient is used to it, and would miss it, and unless there are signs of cardiac failure. The "depressing expectorants," so-called, are the drugs to use in the acute stage. Ipecacuanha is especially useful. Carbonate of ammonium should not be used. The chest should be protected from draughts. There is no advantage gained by putting the patient in a so-called pneumonia jacket. Applications to the chest are old remedies and ones in which the public have very firm belief, but in the opinion of a large number of the profession they are of doubtful utility. There is something to be said for the reflex effects, induced by the application of heat or cold to the chest wall, on the bronchial mucosa. Heat and cold probably act in a similar manner. Cold is more easily applied and incites deeper inspiration. It can be applied in the form of a wet pack. It should cover the front and back of the chest and be changed at frequent intervals. Heat may be applied in the form of a linseed meal poultice. Where the heart shows signs of flagging, strychnine and digitalis should be freely used. Liquor Atropinæ in 1 min. doses every four hours is useful in checking the secretion where this is too abundant.

Chronic Bronchitis is a condition in which it is more necessary that the patient should be treated and not the disease. All cold, wet and fog should be avoided, and where possible the subject of this affection should winter in a more favourable clime than these isles offer, such as the south of France or Egypt. If the patient is unable to leave home, no effort should be spared in doing all possible to improve the general health. Abundance of fresh air and outdoor life should be enjoined. Mouth breathing should be avoided, the diet should be ample but simple—it is best to abstain from alcohol altogether. Cod-liver oil is of benefit in cold weather. Tepid and cold sponging are advisable. If the secretion is scanty and tenacious, ammonium carbonate and iodide of potassium should be given. The latter drug will often act like a charm. The use of alkaline fluids in a fine atomiser will often render the secretion less scanty.

Expectorants that may be prescribed with advantage are: terebene 10 min., creosote 2 min., copaiba balsam in 5 min. capsules. A very useful remedy is the old B.P. Pilula Ipecacuanhæ cum Scilla. Every grade is to be found between a mild case of bronchitis and bronchiectasis. For the irritating cough of chronic bronchitis, no better remedy is to be found than the linctus prescribed by the late Dr. Gee, consisting of equal parts of compound tincture of camphor, oxymel of squill, and syrup of tolu. The dose is 1 dr., and it may be repeated at short intervals until the cough is eased. The objection to the free use of this linctus is that it induces constipation and disorders of digestion. A valuable prescription is the following—

> ℞ Ammonii Carbonatis gr. v
> Tincturæ Scillæ ♏ xv
> Infusionis Senegæ ℥ ss
> Aquam Chloroformi ad ℥ i
> thrice daily after meals.

In children it is often advantageous to give an emetic (*e.g.* a drachm of Ipecacuanha wine), the bronchial tubes being reflexly emptied when emesis occurs. Any form of respiratory gymnastics is of value, and a chronic bronchitic may often derive great benefit from calisthenic exercises with Indian clubs in the fresh air for fifteen minutes daily.

Bronchitis occurring in the course of morbus cordis, gout or renal disease, will be relieved by treating the underlying cause. If expectoration is difficult it may often be helped by constricting the lower zone of the thorax with a band, thus diminishing the thoracic outlet and giving the diaphragm more room for play.

Insomnia is frequent with chronic bronchitis. It is often much relieved on the institution of general treatment. A hypodermic injection of strychnine last thing at night will often act as an hypnotic. A glass of milk sipped slowly at bedtime will often induce sleep. Alcohol will often have the same effect, but in the opinion of the writer it is best avoided in the treatment of this disease.

Paraldehyde in doses of 1 or 2 dr. is an excellent hypnotic. It has the advantage of being a mild expectorant and not depressing the heart. Its nauseating taste is its chief drawback. The bromides must be used in full doses to derive benefit from them. Opium as a routine is, of course, to be avoided, but if used the most useful form is that of Dover's powder in doses of 15 gr. Opium in any form is contra-indicated when this disease occurs in old people, in those suffering from marked emphysema and in children.

If it can be shown that there is a large predominance of one infecting organism the

resolution of the process may be considerably helped by giving small doses of a specific vaccine repeated at intervals of two days.

Fibrinous (Plastic) Bronchitis.—In this affection the bronchial exudate is coagulable and takes the form of solid casts of the bronchial tree. There is nothing definitely known with regard to its pathology. It has been found in association with a great variety of affections of the lung and heart, and with certain general diseases such as the specific infectious fevers. It occurs perhaps most commonly in the course of diphtheria and lobar pneumonia. The presence of bronchial casts in the sputum, together with the occurrence of dyspnœa and cough, are the distinguishing features. Hæmoptysis may be present. There is usually some fever, and the physical signs found in the chest are very variable. These signs are confined to one part of the lung—the signs may vary from a few râles to those of complete consolidation with suppression of breath-sounds. The finding of bronchial casts in the sputum makes the diagnosis certain. There is a great tendency for the disease to recur. Treatment should be carried out on the same lines as in a case of simple bronchitis. There is no specific for this condition. Potassium iodide in full doses may prove of great benefit. Inhalations of steam either alone or medicated with compound tincture of benzoin or creosote vapour materially assist the expulsion of the casts. Oxygen should be given where there is marked dyspnœa. Any associated disease such as morbus cordis or pulmonary tuberculosis should receive appropriate treatment.

Spasmodic Asthma as a clinical entity is to be distinguished from the symptomatic form which occurs in association with other diseases such as affections of the heart and kidney. Spasmodic asthma is characterised by attacks of dyspnœa occurring in paroxysms coming on for some apparently quite inadequate cause, and usually occurring in those with nervous instability. The attacks are accompanied by vasomotor and secretory disturbances, the mucous membrane of the respiratory passages throughout showing sudden hypersecretion. There is no exact pathology known. It often runs in families, but often there is no evidence of heredity. It frequently occurs along with other family diseases such as migraine and epilepsy. It affects the two sexes about equally; it may occur at any age, though in children it is more common in the female. It often accompanies, and is excited by, some catarrhal condition of the respiratory mucous membrane. The attack may be excited by the inhalation of some substance suspended in the atmosphere, such as pollen or dust. The mild catarrhal infection of the nasal or bronchial mucous membrane is often sufficient to excite an attack. Flatulence, constipation or indigestion may induce an attack. Climate and season have a varying influence, some patients being well only when living by the sea, others only in the country air, and yet others only when in the smoke and dust of the large towns. A case may be quoted of the physician who had two asthma patients under his care, the one complained that a smoky chimney brought on an attack, the other took steps to make his chimney smoke because he said that was the only way in which to get relief ! In a typical attack of spasmodic asthma the diagnosis is seldom in doubt. It is paroxysmal and sudden in onset. The expiratory dyspnœa of prolonged expiration, the fixed chest in a position of expiration, are all characteristic. Curschmann's spirals and Charcot-Leyden crystals, together with eosinophiles, are frequently found in the early sputum. The attacks are rarely, if ever, fatal.

Asthma is a capricious disease, and as such requires very varying treatment. Every drug in the Pharmacopœia has at one time or another been proclaimed as a cure for asthma. Treatment should be directed, as far as possible, towards the finding and removing of the exciting cause. Any focus of catarrh or deformity in the mucous membrane of the nasal cavities, larynx or trachea, should receive appropriate treatment. The teeth, stomach and digestive organs must be carefully regulated. The regular use of cold sponging or cold baths may be of much benefit.

The paroxysms may be so great that prompt relief is necessary. There is but one drug which commands the situation, that being morphia. A hypodermic injection of $\frac{1}{6}$ gr. will relieve the attack almost at once. The injection may have to be repeated. If there is much bronchial secretion present, and especially if accompanied by emphysema, morphia may be highly dangerous. A grave objection to the use of morphia is the institution of the habit. It should, therefore, never be used excepting in extreme urgency. According to Brodie and Dixon, atropine should be an effective remedy in relieving pain. It should be given in doses sufficiently large to produce a physiological effect. Inhalation of chloroform or ether are very efficacious, but the relief afforded is but transient. Nitrite of amyl gives temporary relief; heroin may be used as a substitute for morphia. Cocaine also is efficacious as a hypodermic injection. None of the above remedies should be left in the hands of the patient. They should always be given by a trained nurse or by the medical attendant himself.

Inhalations and fumigations are largely used. A very good powder is the following—

Potassium nitrate,
Lobelia in powder,
Powdered Stramonium leaves,
Anise fruits in powder.
Of each one ounce.

Dissolve the potassium nitrate in 1 fl. dr. of water, mix thoroughly with the powder and dry. One drachm of the above is set fire to and the fumes inhaled at frequent intervals. This remedy will be found efficacious in the majority of cases and may be left in the hands of the patient. Many of the proprietary preparations on the market have the above as their chief ingredients.

Alcohol must be mentioned as a remedy, but the risks involved in prescribing it are obvious. Hot rum and milk, hot whisky water and lemon are very useful forms. Where the attack is incited by a large or indiscreet meal, it may often be cut short by the induction of vomiting. The inhalation of steam is often efficacious and should be resorted to if no other remedy immediately offers. Vapourised iodine is a very useful remedy. It may be used in the form of a spray, the iodine being dissolved in potassium iodide and acetone in such proportions that free iodine is present.

Spirone is a preparation on the market which has the following formula—

Acetone 40 parts
Iodine 2 parts
Hyposulphite of Potash 3 parts
Glycerine 20 parts
Water 40 parts.

One drachm of the solution is mixed with 1 dr. of water and used in the form of a spray. The patient should be directed to inhale during the spraying in order to draw the vapour into the main bronchi.

Tucker's inhaler is now so well known that it must be mentioned. Its continuous use is not to be recommended. A somewhat similar preparation is—

Atropine gr. $\frac{1}{3}$
Cocaine Hydrochloride gr. ii
Hyponitrous Acid Gas to saturation
Neboline (Oppenheimer's), to ℥ i

It is used as an oily spray.

Adrenalin in 10 min. doses of the 1–1000 solution given hypodermically is often of great value in relieving an attack of asthma. The relief afforded is only temporary.

The application of the faradic current along the line of the vagus nerve in the neck is recommended.

The two drugs which stand alone in the treatment of this disease between the paroxysms are potassium iodide and arsenic. The iodide should be given in 5 gr. doses three times daily, and its use should be continued for long periods. It may with advantage be combined with arsenic, as in the following prescription—

℞ Potassii Iodidi gr. v
Liquoris Arsenicalis ♏ iii
Aquam Camphoræ ad ℥ 1
three times a day after meals.

With regard to the locality in which to live, every patient is a law unto himself. For the most part, a dry sandy sub-soil in a pine district is found most beneficial. All possible steps should be taken to eliminate any source of mental irritability or worry.

In the intervals between the attacks the patient's life and habits should be carefully regulated, great care being taken to eliminate all possible exciting causes. The diet should be inquired into. The chief meal should be arranged at midday and all indigestible articles withheld.

In young and robust individuals very great benefit is often derived by starvation diet. The writer knows of an asthmatic who observed that the frequency and severity of his attacks bore a direct relation to the quantity of food taken. He found that the less food he took the fewer attacks he had. Finally, the plan was adopted of starving himself for ten days on end, water being the only article taken. Potassium iodide in 5 gr. doses were taken three times daily. By this line of treatment the asthma has been entirely eliminated. After such a course the return to ordinary diet must be a very gradual one. Constipation should be relieved and a high standard of general health and vigour maintained. Everything should be done to exclude attacks of bronchial catarrh. Cod-liver oil should be prescribed in cold weather. The patient's bedroom should be maintained at an equable temperature. If there is a tendency to bronchial catarrh, the temperature of the room should be raised and maintained at or about 60° F. throughout the night. It so often happens that the room is warmed at the time of retiring, the fire is allowed to go out, the temperature of the room falls about 4 a.m., the patient wakening with a severe paroxysm upon him. In cases without a tendency to bronchitis, cold air may be freely admitted, and indeed such individuals will often complain of suffocation should the window be closed.

During the intervals between attacks, regular breathing and calisthenic exercises should be practised daily.

Bronchiectasis.—Bronchiectasis was described by Laennec as long ago as 1808. This is a disease in which there occurs a more or less marked dilatation of the bronchial tubes,

localised or diffuse. Rarely the condition may be congenitally present. More usually it occurs secondarily to some disease of the lung or pleura. As a consequence of this dilatation, the bronchial secretion accumulates and undergoes decomposition, and owing to absorption of products so formed a great variety of untoward symptoms arise. The condition may occur in association with any disease of the lungs and bronchi in which the deeper structures of the bronchial tubes are involved, such as bronchopneumonia, pulmonary tuberculosis, new growth, fibrosis of the lung, pneumonokoniosis, foreign body in the lung. It is rare after a simple bronchitis in which there is catarrhal inflammation only, though a persistent influenzal infection may give rise to a condition of bronchiectasis. Clinically, a patient with bronchiectasis appears cachectic and ill. There is not as a rule any loss of flesh. Paroxysms of cough, with copious and offensive sputum, are the chief symptoms. They are most marked on rising in the morning; if the cavities are full the cough is started by some change in position which causes dislodgment of secretion. Expectoration is usually free. There may be hæmoptysis. Fever is usually absent. There is marked clubbing of the fingers. The physical signs in the lungs vary, and are in the main dependent upon the associated conditions. Death usually occurs from the supervention of some complication such as bronchopneumonia or gangrene of the lung.

Treatment should be directed towards lessening the secretion and rendering it less septic. It is obviously impossible to cure the bronchial dilatations. The patient should live in the purest air possible. This improves the general health, diminishes the amount of organisms inspired and strengthens and deepens inspiration, so that secretions are the more easily expelled.

The patient should make attempts to empty the cavities by changes in position. The body should be inclined over towards the sound side with the head lowered, thus the secretions are encouraged to drain out of the affected area, and on reaching normal ciliated epithelial lining spasms of coughing are excited and the secretions thus expelled.

Inhalations are of the greatest value. The usual substance inhaled is some form of coal-tar preparation, creosote being a very favourite remedy. A small room in the patient's house should be set aside for the purpose, all openings about the fire-place, doors, windows, ventilators being sealed off. A sufficient quantity of creosote is then heated in an evaporating dish by a spirit lamp and the fumes thus allowed to permeate the room. The amount of evaporation which is allowed to take place is regulated by the amount of irritation the patient can stand, tolerance increasing day by day. As the vapour is a strong irritant the eyes and nose require to be protected, the eyes by means of motor goggles, sealed down with adhesive plaster, and the nose by means of plugs of cotton-wool. The patient should stay in the room until the cough is sufficiently excited and secretion sufficiently profuse—twenty minutes or so. This should be repeated day by day. Under such treatment the secretion becomes less fœtid and less in quantity. The respiratory capacity is increased so that the patient is capable of greater exertion without attacks of dyspnœa; the general health is much improved. The chest may show evidence of empty cavities, the signs of which were absent before.

Treatment by intratracheal injections is another method which has for its object the rendering of the cavities aseptic. The usual injection consists of—

Menthol 10 parts
Guaiacol 2 parts
Sterilised Olive Oil 88 parts

With an intratracheal syringe 1 dr. of this mixture is injected daily, care being taken to introduce the nozzle of the syringe below the vocal folds. This is not an easy matter, but with a little practice there ought not to be much difficulty. The essential oil in the fluid partially evaporates as soon as it reaches the trachea and bronchi. The vapour freed thus acts as an antiseptic to the foul secretion, stimulates inspiration and causes the lungs to undergo a great expansion. Secretion is thus more easily expelled. Five per cent. of iodoform emulsion may be used instead of the above mixture, and it has the advantage of being less irritating. Antiseptics injected hypodermically or taken by the mouth have nothing to recommend them. Direct injection into the lung through the chest wall has been attempted, but this is not advisable.

Surgical drainage of the cavities has been tried in a few instances, but the results have been for the most part disastrous. The danger from hæmorrhage, the infrequency of a single cavity and the difficulty in localising this cavity, all offer objections to this method. If the cavity lies near the surface and the lung is fixed to the chest wall by dense adhesions, surgical interference is justifiable.

Attention should be paid to the general health.

The pathology of the condition should always be investigated. The number of organisms which have been grown from the secretions of bronchiectasis is legion. Among the more common ones are the streptococcus, staphylococcus aureus, Friendländer's pneumo-bacillus,

Micrococcus catarrhalis and many non-pathogenic varieties. Rarely the Bacillus coli has been found; the pneumococcus does not commonly occur in the old-standing cases. With regard to the value of specific inoculation, there is no doubt that if it can be shown that one organism largely predominates in the secretion, specific inoculation will help; the doses should be gradually increased until quite large ones are given.

Vaccines in the treatment of bronchiectasis have been, and are being, severely criticised as an effective therapeutic measure. This is largely due to the careless administration and to the fact that due emphasis is not always laid upon the value of inoculating only when there is one largely predominating infection present.

The teeth and digestive organs should be kept in the best order possible, and throughout the colder months of the year cod-liver oil should be taken. All excesses and fatigue should be carefully avoided. For those who can afford it, the dry climate of Upper Egypt is perhaps the most desirable spot the world over for such a patient to winter in. In England, Bournemouth and the south coast are to be preferred. With care a patient with bronchiectasis may live a great many years.

The more diffuse the process causing dilatation, the more dangerous, so that the more favourable cases are those resulting from some localised condition such as pleural effusion or a localised inter-lobar empyema. H. P.

DISEASES OF THE LUNGS

Bronchopneumonia.—This disease consists in the combination of acute bronchitis and bronchiolitis with inflammation of some of the alveoli of the lung. In a few cases it is a primary disease, due to the *Diplococcus pneumoniæ*, and resembles lobar pneumonia in its course and in the treatment it requires (see *Pneumonia*). But in the large majority of instances it is secondary to bronchitis, and caused by the spread of an already established inflammatory process from the bronchi to the bronchioles and thence into the alveoli. The alveolar consolidation that results is always associated with a good deal of alveolar collapse, due to inflammatory blocking of a number of the smaller bronchi and the absorption, by means of the blood-stream, of the air contained in the alveoli to which they lead. In consequence it is often impossible to say at what point, in the course of an attack of acute bronchitis that turns to bronchopneumonia, the transition from the one to the other is effected, or whether or no the case is to be regarded as one of capillary bronchitis at some stage of its course. In a general way the diagnosis of bronchopneumonia is made by observing a gradual increase in the severity of the bronchitic patient's symptoms, the irregular fever and the dyspnœa increasing, and by the appearance of physical signs suggesting that patches of consolidation and of collapse are present in the lungs as well as bronchitis or bronchiolitis. Bronchopneumonia is a common and very fatal disease during the first four or five years of life, often complicating the bronchitis of one of the acute specific infectious fevers, particularly whooping-cough, measles, and diphtheria. It is also common in the aged, again as a complication (often terminal) of bronchitis. It may occur at any age as the result of the inhalation of infected solids or liquids into the bronchi ("inhalation-pneumonia," "aspiration-pneumonia," considered separately below), and this is the only form of bronchopneumonia that is not rare in adolescents and adults.

The main indications for treatment in bronchopneumonia are two—

1. To facilitate coughing, and the expulsion of secretion that tends to block the air tubes and so to bring about death by asphyxia.
2. To maintain the strength and resisting power of the patient throughout an exhausting disease that is likely to last for several weeks.

The patient should be kept in bed in a room at a temperature of 60°–65° F., and given plenty of fresh air while protected from draughts. It is most important that the sick-room should be well ventilated and its atmosphere prevented from becoming stale or close; to have the patient in bed out of doors is an excellent plan when the weather permits. The bed-clothes should be light but warm. Poultices applied to the chest and back have often been recommended, but have the disadvantage of being heavy and close-fitting, and so tending to cramp the respiratory movements. Anything that interferes with the free play of the lungs in bronchopneumonia is bad for the patient, and loose cotton-wool or Gamgee-tissue jackets are, therefore, more generally useful than poultices in this complaint. Anything that makes a child with bronchopneumonia cough and expectorate, and expands the collapsed portions of its lungs, is good, and the disturbance caused by examining and auscultating it, or by lifting it out of bed and carrying it about in the arms, often proves beneficial by bringing on a paroxysm of coughing. In the same way hydrotherapy is of service; for example, the child may be immersed in a very hot bath (4 gallons of water at 106°–108° F.) with a tablespoonful or two of mustard in it for a minute or two, then taken out, dried rapidly, and put back to bed.

Cold water may be splashed on its face while it is in the bath. A child that is less ill or stronger often benefits more by a cold bath than by a hot; the object is to increase the depth of the breathing and to slow both pulse and respiration, and the danger is lest the shock and chill of a cold bath or cold pack should enfeeble the heart's action and make the child pale, cyanosed and chilly. Hot and cold packs or alternate douches with hot and cold water are often worth trying, particularly in the cases with high fever and delirium.

The diet should be entirely in the form of liquid or slops, and every effort should be made to get the patient to take as much food as possible. It is particularly in the older patients that difficulty is experienced here, although the need for keeping up the strength is greater in the aged than in the young. Food should be given in small quantities and at frequent intervals—every two hours or less; milk, soups, broth, eggs in any form that is acceptable, mild stimulants such as tea, coffee, cocoa, and the diluter foods like lemonade, barley water, Imperial drink, may all be tried. It is generally best to give all these drinks hot, as their heat may aid the patient in getting rid of the bronchial secretion. More solid foods may be given as the appetite returns and the dyspnœa lessens. As regards alcohol, modern practice is perhaps less opposed to its employment than it was a few years ago. Most children and all old persons with bronchopneumonia are the better for alcohol, generally in the form of whisky or brandy, sometimes as champagne. A child of one may have 15 min. of brandy or ½ dr. of port wine every two hours; an adult half a pint of champagne or from 2–4 oz. of whisky in the twenty-four hours.

The drugs indicated are mainly those that promote bronchial secretion and those that stimulate the action of the heart. The following prescription gives an example of a stimulating expectorant in bronchopneumonia—

℞ Ammonii Carbonatis gr. i
Vini Ipecacuanhæ ♏ iii
Glycerini ♏ xv
Aquam Anethi ad. ʒ i.

Ft. Mist. One teaspoonful to be taken every four to six hours by a child under four; two teaspoonfuls similarly by a child from five to twelve.

In a general way the use of sedatives is to be deprecated, and is contra-indicated if there is cyanosis. But if the cough is very harassing it may be wise to add some form of opiate to the mixture, such as paregoric (Tinct. Camph. Co. 2–10 min.) or codeia ($\frac{1}{50}-\frac{1}{15}$ gr.), according to the age of the child, ceasing to give it as soon as the necessity has gone. For an adult, the prescription may read—

℞ Ammonii Carbonatis gr. iv–viii
Vini Ipecacuanhæ ♏ x
Syr. Papaveris ʒ ss–ʒ i
Aquam Camphoræ ad. ℥ i.

Ft. Mist. Two tablespoonfuls to be taken every four to eight hours.

Ammonium chloride is a useful expectorant, and may be substituted (in double the dose) for the carbonate in the above mixtures.

The use of the steam-kettle and of inhalations of medicated steam is often advisable in bronchopneumonia, and may be tried empirically and for so long as it seems to give the patient relief. It is indicated when the bronchial secretion is scanty, and should be stopped if the patient becomes cyanosed or the expectoration copious. The steam-kettle, or inhaler, should contain a drachm of Tinct. Benzoinæ Co., or a drachm of a mixture of this tincture with Oleum Eucalypti and Oleum Pini Sylvestris in equal parts, to a pint of hot water. It should not be used continuously. In the very severe cases when there is much dyspnœa, inhalations of oxygen, or of oxygen that has been bubbled through a strong solution of alcohol or brandy, and is in consequence charged with some vapour of alcohol, may be tried. But it must be confessed that oxygen inhalations often prove disappointing in bronchopneumonia, as if the gas failed to reach the alveoli of the lungs in any appreciable quantity.

Cardiac stimulants are generally necessary to maintain the action of the over-taxed right ventricle, which tends to fail from general toxæmia and want of aeration of the blood on the one hand, and on the other from obstruction to the circulation through the lungs. This is particularly the case with the aged patients, who should receive stimulation early in the disease. Digitalis should be exhibited in some form—Digalen, or Nativelle's crystallised digitaline; or strychnine—

℞ Liquoris Strychninæ ♏ iii–viii
Acidi Phosphorici Diluti ♏ xv
Inf. Gent. Co. ad. ℥ i.

Ft. Mist. For a child of two, one teaspoonful every six hours; for an adult, two tablespoonfuls three or four times a day.

In many cases the stomach is upset, and it is therefore better to give as few drugs by the mouth as possible; such stimulants as strychnine, caffeine and camphor may then be given subcutaneously. Camphor, much employed as a cardiac stimulant subcutaneously on the Continent, may be injected in the form of a 10 per cent. solution in olive oil, sterilised by

heat; or a mixture of three parts of camphor in twelve of almond oil and eight of ether may be employed for deep subcutaneous or for intramuscular injection. In either case the injection may be given freely, the patient receiving as much as 10 or 20 gr. of camphor in the twenty-four hours.

To promote expectoration in children judged strong enough to stand the treatment, emetics may be given. A drachm of Vinum Ipecacuanhæ may be given, and repeated every ten minutes until the child is sick; 5 gr. of copper sulphate may be given, and this drug is less depressing to the heart than ipecacuanha.

The after-treatment of bronchopneumonia demands more attention than it usually receives. In many cases the patient is left with a marked tendency to recurrent attacks of bronchitis, or with chronic bronchitis and emphysema. In others the resolution of the bronchopneumonia is delayed or imperfect, with the result that fibrosis of a more or less extensive amount of the consolidated or collapsed lung-tissue ensues, with its liability to the development of bronchiectasis. In others again pulmonary tuberculosis appears during convalescence. Special care should therefore be taken to fend off all these forms of weakness of the lungs so far as is possible. Convalescence after bronchopneumonia should take place in good country air, and be prolonged for as many months as may prove necessary for the clearing up of all pulmonary signs and symptoms. Breathing-exercises should be advised at first, or for longer periods in cases where regular and graduated out-door exercise is not available. Cod-liver oil in one form or another should always be given, and a tonic containing nux vomica often improves the appetite and with it the general condition. The more the child is out of doors the better; to ensure its proper clothing and prevent its being too warmly dressed and coddled in flannel will often entail severe struggles with nurses and fond parents, who seek to protect the patient from chills by overloading it with woollen garments.

Inhalation-pneumonia, also known as aspiration- or deglutition-pneumonia, follows the entry of septic matter or foreign bodies into the bronchi. Such matter may be a quantity of food or drink that has been swallowed the wrong way; water that has somehow got into the bronchi during diving or bathing; mucus, or gastric contents, or septic material from buccal or nasopharyngeal lesions, that may have been aspirated into the lungs by persons while drunk or patients under the influence of a general anæsthetic. Less often the septic material gets into the bronchi through a tracheotomy wound, or through an œsophago-tracheal fistula in patients with cancer of the œsophagus; by patients with ulceration or destruction of the epiglottis and the tissues at the back of the tongue food may be swallowed directly into the trachea. The bronchopneumonia that follows the aspiration of such materials is commonly a severe and rapidly fatal process, owing to the virulence and variety of the micro-organisms they contain. The main indication for treatment is to support the patient's strength with food at short intervals and with stimulating expectorants, in the hope that the infecting matter may be either expectorated or rendered innocuous by the patient's organised powers of resistance. Not infrequently inhalation-pneumonia turns to gangrene or abscess of the lung, and becomes amenable to surgical treatment. The reader is referred to the articles on *Gangrene of the Lungs* and *Abscess of the Lungs* for further information.

The Fibroses of the Lung.—Chronic pulmonary tuberculosis is by far the commonest cause of fibrous change in the lung, but it is not to be included among the causes of the comparatively rare condition known clinically as "fibrosis of the lung." In the same way the diffuse fibrosis of the lung met with in pneumoconiosis, the infection of the lung with dust or powdered minerals occurring in certain occupations, is to be excluded from consideration here. The condition may, therefore, be further defined by saying that it consists in an extensive and non-tuberculous fibrosis of the lung-tissue; and that it is due to arrested recovery from bronchopneumonia in over half the cases, in most of the remainder to delayed resolution of lobar pneumonia, pleurisy with effusion, empyema, and in a few instances to adherent pleurisy, prolonged bronchitis, pulmonary collapse, syphilis, and perhaps trauma. It is always a legacy left by some other pulmonary affection, and there is no reason to suppose that it is ever a primary disease. Except in some few of the cases arising from bronchopneumonia it is unilateral.

No drugs or treatment are known that will cause the absorption of the fibrous tissue deposited in the affected lung. The patient's chief complaints are two—chronic shortness of breath on the one hand, chronic cough and expectoration on the other. The shortness of breath is no doubt mainly due to the loss of active lung-tissue caused by the fibrosis, and should be combated by breathing-exercises and by a prolonged course of graduated physical exercises. It is surprising to see how successfully compensation for the loss of lung-tissue can be effected in working people with fibrosis of the lung, who have been compelled by the pressure of circumstances to earn their living by their own exertions. A second cause for the shortness of breath lies in failure of the right ventricle of the heart. This is met with either early in the case, when the patient over-exerts

himself before the heart has had time to accommodate itself to the altered state of the pulmonary circulation, and the increased resistance to the passage of the blood through the lungs, or else later and as a result of the strain put upon it by the patient's chronic bronchitis. It must be treated by cardiac tonics, of which the most important is digitalis (for example, Tinct. Digitalis 5–10 min. three times a day, one perle of Nativelle's crystallised digitalin once, or perhaps twice, a day, Digalen 5–10 min. two or three times a day), and an effort should be made to lessen the associated bronchitis.

Sodium benzoate in large doses (30–150 gr. a day) has been highly recommended for the treatment of pulmonary fibrosis; I have found it disappointing. The patients are particularly liable to attacks of bronchitis, and to the development of bronchiectasis in the fibrotic parts of their lungs; for the treatment of these complications see *Bronchitis* and *Bronchiectasis*.

Prophylaxis.—Once established, fibrosis of the lung is a very chronic, and frequently a troublesome, complaint. It is probable that its occurrence could often be prevented if greater care were taken with the convalescence of patients attacked by bronchopneumonia, lobar pneumonia, and pleural effusion, in whom resolution of the inflamed lung-tissue or re-expansion of the collapsed lung are delayed. It is highly important that these patients should not be got out of bed too soon, or sent back to school or to work while the physical signs of collapse or consolidation of the lung persist. Breathing-exercises should be given several times a day to aid the re-expansion of the affected part of the lung. Complicated apparatus of any kind is unnecessary; it suffices that the patient should stand up and breathe deeply and regularly, raising his extended arms above his head and rising on his toes as he inspires, lowering the arms to his sides and bending his knees as he breathes out. Expansion of both the lungs may be encouraged by making the patient blow water from one woulfe's bottle into another by the air-pressure raised in his lungs. Expansion of one lung can be aided by throwing on it the chief burden of respiration. This may be done by firmly strapping the sound side of the chest, and renewing the strapping when it works loose; or, more simply, and therefore better, by making the patient sit sideways in a chair clasping the back of it firmly to the sound side of his chest, thus limiting the respiratory movements of the sound side and increasing the work of the affected side, for periods of from ten to thirty minutes several times a day. When in bed he should be similarly encouraged to sleep lying on the sound side of his chest.

Emphysema consists in a permanent enlargement in the size of the lungs, with enlargement in size and diminution in number of the pulmonary alveoli, and loss of the elastic tissue in the lungs. In many cases it is due to over-use of the lungs, as occurs in patients with chronic bronchitis who cough a great deal, in glass-blowers and players of wind-instruments. In some instances of chronic bronchitis and spasmodic asthma it is due to over-forcible inspiration; and it is possible that in a few cases emphysema of the lungs is secondary to enlargement of the bony and cartilaginous cage of the thorax.

Treatment in emphysema is directed to the relief of two main complaints, shortness of breath and bronchitis. The shortness of breath is generally due to the smallness of the respiratory excursions the enlarged lungs are able to make; their vital capacity may be reduced to one or two litres, in place of the normal three or four litres, with the result that any slight extra-exertion finds the patient out of breath, unable to breathe deeply and so forced to breathe fast. The only treatment that is likely to do good here is the employment of breathing-exercises, the arms being raised during inspiration, lowered and pressed against the side during expiration in such a way as to aid the expulsion of air from the lungs. The patient should be directed to give particular attention to the expulsion of air from the lungs, as lack of expiratory power is one of the chief features of his complaint. In long-standing cases of emphysema the shortness of breath is often cardiac in origin, due to failure of the right ventricle; for the blood pressure in the pulmonary artery is much raised in emphysematous patients, as the resistance to the passage of blood through the lungs is much increased. The treatment here is to give cardiac tonics, of which digitalis is by far the best. Often the patient will be unable to lie down in bed at night, preferring to sleep in a chair with his legs down. Strychnine and small doses of morphine hypodermically (Injectionis Morphinæ Tartr. 1–3 min.) may be given cautiously in these instances, as these patients suffer much from the nervous exhaustion due to want of sleep.

The acute and chronic bronchitis to which emphysematous patients are so very prone must be treated on general lines (see *Bronchitis*). Ammonium carbonate or chloride, with or without ipecacuanha, are the drugs chiefly indicated—

℞ Tinct. Nucis Vomicæ ♏ v
Ammon. Carbonatis gr. iv–viii
Tinct. Scillæ ♏ xv
Spir. Chloroformi ♏ xv
Infusum Senegæ ad ℥ i.

Two tablespoonfuls to be taken three or four times a day. Potassium iodide (2–5 gr.) is useful in the cases with hard, dry cough and deficient secretion; Tinct. Belladonnæ (5–15 min.) in those with profuse expectoration.

In a general way, and in the intervals when they are free, or comparatively free, from bronchitis, emphysematous people are the better for taking drugs, particularly arsenic (Liquoris Arsenicalis 1–3 min.) and potassium iodide (2–4 grs.), three times a day; the latter is particularly serviceable in the cases with high arterial tension due to arteriosclerosis, or with liability to attacks of spasmodic asthma. The tendency of a patient taking small doses of arsenic for long periods to develop arsenical pigmentation, neuritis, or hyperkeratosis of the palms and soles, must not be forgotten, and both the arsenic and the iodide may be given in courses of a month's duration with intermissions of a month.

The climatic treatment of emphysema is of importance among the well-to-do, who travel long distances to avoid the rigours of an English winter. If the patient has much associated bronchitis and expectoration a warm and dry place is to be recommended, and may be found in the Italian Riviera, Sicily, Egypt. In the drier cases, where there is little expectoration, though the cough may be obstinate, a damper climate is to be advised, such as Madeira, Algiers, Pau, Arcachon, or the seaside resorts of the south and south-west coasts of England—Bournemouth, Ventnor, Falmouth, Torquay, St. Ives. Not a few emphysematous people are reduced to wintering indoors; and not a few find the climate of London, with all its faults, more suitable than any other. Individual experience is without doubt the safest guide here.

Two other methods of treatment in emphysema remain to be mentioned. One is treatment by the respiration of compressed air, the other is treatment by surgical operation. The compressed air treatment consists in placing the patient in a small room in which the pressure of the air can be gradually raised until it is from five to ten or fifteen pounds per square inch higher than the atmospheric pressure outside. This raising occupies half an hour; the pressure is maintained for an hour, then lowered in half an hour to the normal once more. The patient takes one of these compressed air baths a day, and goes in for a course of twenty or thirty of them. A constant supply of fresh air must be kept up while the bath is in use. The way in which these baths do good is disputed; in many cases of emphysema they prove useless, but in the minority the patient feels better, breathes more easily and suffers less from bronchitis after he has had them, and their good effects may persist for many months. The treatment is contra-indicated in cases with disease of the heart or kidneys, or with profuse expectoration. It is free from danger, and is always worth trying when available. The treatment of emphysema by surgical operation—Freund's operation—is more questionable. The operation consists in the removal of an inch or an inch and a half of the second, third, fourth and fifth costal cartilages on one side of the chest, or, in a few instances, on both sides. The object is to destroy the rigidity of the emphysematous thorax, and so to increase the vital capacity of the lungs; great care must be taken not to open the pleural cavity. A number of favourable results have been recorded on the Continent; the inspiratory expansion of the patient's chest has increased from ¼–1 inch to 1–3 inches in favourable cases, and the patient has been much more comfortable and less short of breath. In this country the results of Freund's operation have not been so satisfactory, and it must be regarded as still on its trial. It is indicated in patients who have very large and rigid barrel-shaped chests.

Gangrene of the Lung—a fortunately rare complaint, occurs most often as a complication of bronchopneumonia due to the aspiration of septic matter into the bronchi. It may follow lobar pneumonia in debilitated or diabetic patients, and is also met with if the putrefying contents of a tuberculous or bronchiectatic cavity in the lung by some mischance are spread into the lung by coughing. It is recognised by the copious expectoration of sputum with a penetrating and peculiarly disgusting odour, and by the presence of pulmonary elastic tissue in the sputum.

In many instances pulmonary gangrene is acute, a terminal event, occurring in the wasted victims of œsophageal or lingual cancer, of chronic pulmonary tuberculosis or diabetes. Here treatment can be palliative only. In other instances, however, it is a more chronic affair; and in yet others, those in which it is most amenable to treatment, it is strictly localised in the lung. The chief indications for treatment are both medical and surgical. Medically the effort should be made to lessen the quantity and infectivity of the gangrenous expectoration, and this may best be done by administration of antiseptic inhalations of creosote, eucalyptus oil, carbolic acid and the like. Dundas Grant has recommended the following mixture—

℞ Olei Cinnamomi ♏ v
Menthol gr. x
Ol. Pini Sylvestris ʒ ss
Spiritus Chloroformi ʒ ss
Creasoti ʒ ii.

M. Ten drops to be placed on the sponge of a Burney Yeo's inhaler, and renewed every hour.

In a few recorded instances good results have followed the intra-tracheal injection of a drachm of sterilised olive oil containing 10 per cent. of menthol, the patient subsequently turning on his side so as to aid the flow of this solution towards the gangrenous part of the lung. The subcutaneous injection of these pulmonary antiseptics has not proved successful. But the best results in pulmonary gangrene, the only results that have proved satisfactory in any but the mildest cases, have been those obtained by the use of surgical measures. Garrè's statistics show that out of 281 recorded cases of pulmonary gangrene treated surgically, 197 were cured and 84 (or 30 per cent.) died; medical treatment is said to have a mortality as high as 75 per cent. What the surgeon asks is that there should be definite physical signs localising the gangrenous area in any case that he is to treat by operation; a great deal of help here may be afforded by x-ray pictures. The surgeon's task is much facilitated if, as is generally the case, the gangrene comes to the surface of the lung; and still more if the neighbouring visceral pleura is adherent to the parietal layer in such a way as to lessen the two great dangers of infection of the general pleural cavity and the establishment of a sudden pneumothorax by the operative procedures. Exploratory puncture of a gangrenous lung is most inadvisable, as it has often caused a generalised infection of the pleural cavity. The operative treatment required consists in the resection of a portion of a rib and the establishment of free drainage for the gangrenous material pent up in the lung. The particular dangers of these operations and the precautions to be taken against them must be sought in special surgical manuals in which the necessary surgical technique is discussed.

Abscess of the Lung.—Cases of this uncommon condition may be divided into two classes according to their mode of origin.

1. In the first class are those in which the pulmonary abscesses are multiple, the so-called embolic or metastatic abscesses implanted by the blood, and arise in the course of venous pyæmia, or of malignant endocarditis affecting the right side of the heart. These cases are practically always rapidly fatal; the signs and symptoms are those of pyæmia, with increased shortness of breath, pain in the chest, and cough superadded. Treatment can only be symptomatic and palliative, because surgical relief is impracticable owing to the multiplicity of the abscesses in the lungs. In quite exceptional instances there may be only one or two of these metastatic abscesses in the lungs, and then the outlook is a shade less hopeless because the pyæmic patient may be amenable to surgical treatment.

2. In the second class are the cases in which the pulmonary abscess is single, or perhaps due to the confluence of a number of adjacent abscesses, and due to a local infection of the lung and not to a general pyæmic infection. Such may occur after lobar or lobular pneumonia, particularly after influenzal pneumonia; but the majority of the cases are the result of inhalation-pneumonia, the accidental aspiration of solid or liquid foreign bodies (such as food, drink, saliva, nasopharyngeal secretion, fragments of extracted teeth, and so on) into the bronchi, perhaps while the patient is unconscious or under the influence of an anæsthetic. If large, these foreign bodies are apt to set up an acute localised septic bronchitis at the point where they lodge; if small or finely-divided, an acute septic bronchopneumonia. In either case the condition is likely to pass on into abscess or gangrene of the lung (no clear distinction can be drawn between the two) if the infecting micro-organisms are sufficiently virulent and if the patient does not succumb from exhaustion before there has been time for the abscess to develop. In both abscess and gangrene of the lung the sputum is generally fœtid, often with a very horrible and penetrating odour; it contains larger or smaller shreds of pulmonary tissue in both conditions. Medical treatment is naturally of little avail in abscess of the lung; antiseptic vapours and inhalations (see *Gangrene of the Lung*) may be given as a palliative. Like empyema and gangrene of the lung, pulmonary abscess should be referred to the surgeon for operative treatment as soon as the diagnosis can be made.

New Growths of the Lung may be either innocent or malignant. The latter are either primary, or secondary to malignant tumours elsewhere in the body. The secondary growths are the commoner; they are habitually multiple, and are quite beyond the reach of any medical or surgical treatment at present known to us. Primary malignant new growths of the lung, with which it is clinically convenient to consider many of the primary malignant new growths of the pleura and of the mediastinum that are often found practically to be indistinguishable from them, are not amenable to medical treatment and only in the rarest instances to surgical; they comprise carcinoma, lymphosarcoma and sarcoma. The symptoms of such new growths are generally indefinite—pains in the chest and back, shortness of breath, progressive loss of weight and strength, progressive anæmia, cough and expectoration—as the growth is often situated at the hilus of the lung. For the same reason the physical signs are often late in appearing and inconclusive, though much help may often be derived from x-ray examinations and skiagrams. If the new growth is a carci-

noma originating in the wall of a large bronchus, hæmoptysis may occur and the physical signs suggesting extensive pulmonary tuberculosis may be found; or it may be suspected that the trouble is due to an aortic aneurysm compressing a bronchus. The treatment of such intrathoracic new growths must be almost entirely symptomatic and palliative; a few cases of intrathoracic lymphosarcoma have been recorded in which much temporary benefit resulted from a course of exposures to the x-rays. Recurrent pleural effusions often complicate these cases of malignant intrathoracic new growth. Hence careful watch should be kept to see that the patient is given relief by paracentesis as soon as he is inconvenienced by the accumulation of fluid in his chest. Attacks of spasmodic dyspnœa sometimes occur, and may be relieved by hypodermic injections of atropin (Liq. Atropinæ sulphatis ♏ ss–i–ii) with or without the addition of morphin (Injectio Morphinæ Tartr. ♏ ii–v).

Innocent new growths of the lung, including such benign neoplasms of the pleura and mediastinum as are apt to encroach upon the lung in their growth and so may be clinically indistinguishable, occur but rarely. They consist for the most part of pulmonary fibromas and lipomas, teratomas (or dermoid cysts) of the mediastinum, echinococcal cysts and gummas of both the mediastinum and the lung, fibrosarcomas of the pleura that are but slightly malignant; a number of other very rare forms of tumour have been described. The diagnosis is generally impossible *ante mortem*, except in the case of echinococcal cysts that may be identifiable by the use of the x-rays, or of syphilitic deposits that disappear under the influence of potassium iodide, mercury and salvarsan. Teratomas of the mediastinum have been recognised when they have chanced to burst into a bronchus and their hair-containing contents have been expectorated. As with the malignant new growths of the lung, pleura and mediastinum, medical treatment is useless, and surgical treatment is applicable only in the most favourable cases. A special word of warning as to the dangers of the exploratory puncture of echinococcal cysts may be here inserted. For details of the various operative procedures the reader is referred to the special surgical manuals that deal with the subject. The only exceptions to this rule are the syphilitic neoplasms; in many recorded instances these have yielded to antisyphilitic treatment. It must be remembered that while the diagnosis of intrathoracic new growths is very difficult, to discriminate between their different varieties is generally impossible during life. In all cases, therefore, Wassermann's reaction should be looked for, and if it is positive the patient should receive the benefit of a thorough course of antisyphilitic treatment.

POST-OPERATIVE COLLAPSE OF THE LUNGS

The condition to which this term is applied affects the lower lobes of one or both lungs, and consists in a partial or complete collapse, thus rendering a large amount of lung tissue inoperative. As the causation of the condition appears to be largely of a mechanical nature, it is necessary to consider the mechanism of its production. The expansion of the lower lobes of the lungs is dependent upon two factors, the action of the diaphragm and the movement of the chest wall. The latter is in turn mainly dependent upon the tone of those muscles which connect the thorax to the pelvis and spine, at the same time exercising pressure on the abdominal viscera. Without this abdominal action in the supine position with quiet respiration, the thoracic cage assumes the same position as is produced by a full and forcible inspiration or by emphysema. In the infantile chest or in the case of the adult in whom the thoracic cavity is funnel-shaped, this condition is unfavourable to the action of the diaphragm, but where the shape of the chest approximates to that found typically in cases of visceroptosis, the arch of the diaphragm is not diminished and the muscle contracts well. In patients in whom one-sided massive collapse is detected, the chest on the affected side is found by measurement to be greater than normal, and the abdominal muscles of the same side are toneless. The mechanism of the reflex which governs the contraction of the abdominal muscles in respiration is not understood. In the erect posture the abdominal muscles present a condition of tone, or, in other words, there is some continuous contraction of these muscles during the whole of the respiratory phase. It is, however, well recognised that in the supine position the abdominal muscles show either no tone at all, or very much less tone than in the erect or sitting position. The lower part of the chest dilates and the abdominal viscera therefore gravitate towards the thorax and tend to press the thoracic contents towards the head, and the diaphragm cannot contract to the same advantage. The quieter the respiration the more rapidly will this alteration develop. In such cases the upper lobe is found to be over-expanded and the lower lobe collapsed. This collapse develops slowly, but after twenty-four to thirty-six hours the following signs may be detected. The position of the cardiac impulse moves up to the fourth space, the upper level of the liver dulness begins at the fifth rib, the stomach resonance extends upwards into

the axilla, and the breath sounds become accentuated over the upper lobes, but are faint or inaudible over the lower lobes. In addition, the resonance over the lower lobes is diminished, distant bronchial breathing, altered voice sounds and some crepitations may be detected. The lower part of the thorax is already expanded to its fullest extent, and there is no increased expansion during forced inspiration. In the normal individual the condition is corrected rapidly when the sitting or standing posture is assumed, the reflex which produces abdominal tone coming into play. In some cases of massive collapse in the sitting position the abdominal muscles of one or both sides are quite flaccid and show no contraction during the respiratory phase. The reflex normally present is inhibited. These conditions of increased measurement of the affected side of the chest and associated atonic abdominal muscles have been present in all the cases of massive collapse which I have investigated.

The symptoms exhibited by these patients may be (*a*) none at all, (*b*) shortness of breath when speaking or drinking, or (*c*) attacks associated with marked dyspnœa and coughing and the expectoration of dark-coloured mucus, pyrexia developing subsequently. These latter symptoms are, I believe, entirely due to the inhalation of infected mucus (which is the material expectorated) into a part of the bronchial system previously not involved, coughing and dyspnœa resulting. In these attacks the patients attempt to sit up, and struggle for breath, the dyspnœa being temporarily very marked. The inhaled mucus may set up a septic infection of the bronchial system of the lower lobes, even producing bronchopneumonia.

From this summary it will be seen that collapse of a mild nature is a general occurrence in those who are kept in a supine position, the severer attacks being due to the presence of septic material. The prophylactic treatment, therefore, must be directed against these two factors. (1) Prior to operation every effort must be made to secure a healthy condition of the mouth and respiratory passages. (2) The anæsthetist should use his discretion as to the degree of anæsthesia to be induced when these parts are not in a satisfactory state. (3) Care must be taken that the patient be not exposed to chill during or immediately after the operation. (4) The patient should not be kept in the supine position for more than thirty-six hours after the operation, except in those rare cases when the exigencies of the operation demand it, but on the contrary ought to be encouraged to lie on his side and make spontaneous movements, such as changing his position in the bed, and taking food and liquids unaided. Raising his head brings the recti abdominalis muscles into action. He may also, as soon as possible, be supported by pillows for a part of the twenty-four hours, so raising the body to a reclining posture and negativing the effect of the upward pressure of the abdominal viscera. Tight bandaging of the abdomen has a tendency to increase the inhibition of the action of the abdominal muscles, and should therefore be avoided.

Should collapse be detected, but no symptoms have arisen, similar treatment should be ordered, and in addition the patient should be encouraged to talk. Artificial means for distending the lung may be employed, such as the "blow-bottle" for adults, or blowing bubbles for children. Support by a bandage or roller-towel firmly applied to the lower part of the chest, not to the abdomen, may be tried tentatively. Some patients are relieved by this measure, others will not tolerate the pressure at all or only for a short time.

When the severe type of attack occurs, the patient should be kept sitting or propped up continuously, and assistance to the breathing given by supporting the lower part of the chest, expiratory efforts being encouraged and assisted at intervals by bimanual pressure to the lower thorax. Oxygen may be administered at this time, and the patient should be reassured continually. The feeling of terror at the dyspnœa during these attacks is overwhelming. When indicated, strychnine and ether should be injected. The alarming symptoms may last from a few seconds to three or four hours. When these have passed off the patient should remain propped up with pillows, and if necessary support should be given to the lower part of the chest as mentioned above. The further treatment will depend upon the development of bronchitis or bronchopneumonia (for which see the appropriate section). The sitting position and frequent employment of the abdominal muscles will assist the collapsed lung to expand. When pyrexia with cough and expectoration ensues, blow-bottles, etc., should not be employed, and the patient should be kept quiet, propped up on pillows till the temperature has subsided. Otherwise, more septic material will be inhaled into collapsed areas and the infection will be increased. In a few cases the abdominal reflex is so deranged that in spite of the assumption of the sitting position the abdominal muscles do not come into play during ordinary respiration. Here, again, in the absence of fever, forcible expiratory efforts should be induced by the aid of the blow-bottle, etc. Occasionally, when the lungs remain collapsed for some weeks, deliberate puncture with the exploring needle will initiate recovery.

Some of the other unpleasant symptoms which are liable to follow operations, such as marked distension of the large intestine and dilatation of the stomach containing a considerable amount of liquid, also depend upon this flaccid condition of the abdominal wall, and may assist in promoting the collapse of the lower lobes by impeding the descent of the diaphragm. These should be treated by removing the contents of these viscera by appropriate measures, and adopting the foregoing methods.

J. C. B.

DISEASES OF THE PLEURA

Pleurisy, Dry or Plastic.—This, the simplest form of pleurisy, occurs with various degrees of severity from the fugitive pains met with in cases of tuberculosis of the lungs to instances which closely resemble acute croupous pneumonia. In the mildest cases relief of pain may be obtained by the application of some counter-irritant to the chest wall, as by rubbing with Linimentum Terebinthinæ Aceticum or painting with Pigmentum Iodi—equal parts of the Linimentum Iodi and Tinctura Iodi mixed, the application being made daily, or twice daily, until distinct reddening of the skin persists. The general treatment of the case is that suitable for pulmonary tuberculosis, open air and generous dietary, but if the pain is accompanied by any fever, the patient must be kept in bed. In cases of greater gravity, where the pain is considerable, the simplest means of controlling it is by limitation of the movement of the affected side. For this purpose a strip of lead plaster, two and a half or three inches in width, is cut, long enough to pass round the affected side, and to overlap the middle line at each end, before and behind. To ensure that it will lie evenly in contact with the chest wall it may be necessary to "nick" the lower border with scissors here and there. The plaster is then warmed till it is thoroughly sticky, and is quickly applied, while the patient holds his chest in a position of expiration so as to narrow its diameter as far as possible. In some instances pain is not relieved, and may even be increased by the pressure thus applied. It is therefore advisable to gain some idea as to the applicability of this method by first making steady pressure with the hand over the seat of pain, and ascertaining whether this is comfortable to the patient or the reverse. Sometimes a flannel roller-bandage passed right round the lower part of the chest is serviceable, but it has the disadvantage of impeding the movement of the unaffected as well as of the painful side. Poultices or fomentations applied to the seat of pain are generally useful: the addition of a little mustard to a linseed poultice makes it more stimulating. "Mustard leaves" are convenient substitutes in the absence of facilities for making and changing poultices: they should be moistened with warm water and covered with a layer of cotton-wool and a bandage. The application of a blister sometimes gives relief, the resulting vesicle being opened, and either treated with fomentations, or covered with a thick pad of cotton-wool. An application of antiphlogistine may be made as a substitute for poultices, if it is at hand: it is applied hot and covered with a layer of cotton-wool. On the other hand, an ice-bag or "ice-poultice" is appreciated by some patients: it should not be tried on old or debilitated subjects, but is useful in sthenic cases accompanied by high fever. Finally, the application of six or eight leeches, followed by fomentations, may give great relief. If the pain is very severe, and is not controlled by any of the above measures, opium in some form is necessary. It is best given as an injection of morphine $\frac{1}{4}-\frac{1}{6}$ gr., repeated in an hour's time if necessary; but other forms, such as Pulvis Ipecacuanhæ Compositus may be given if desired. In severe cases accompanied by fever, the general management of the case is similar to that in acute pneumonia. The patient is kept in bed, and given only fluid diet. The bowels should be attended to, and saline or mercurial purgatives are useful at the beginning of the trouble or at intervals throughout. During the acute stage a diaphoretic mixture, such as Potassii Citratis 20 gr., with Liquor Ammonii Acetatis 2 dr., and camphor or chloroform-water to 1 oz., may be given every four hours. As the disease subsides small doses of iodide of potassium are indicated to aid in the absorption of exudate: 5 gr. may be given three times a day, with gentian and nux vomica, or extract of cinchona, or any other tonic that is preferred. The troublesome cough, which is often so distressing in cases of pleurisy, is sometimes relieved by the local applications to the chest already mentioned, but may need the administration of a linctus. A simple linctus such as oxymel of squill, 15 min. and golden syrup to 1 dr. may be sufficient, but more often some sedative must be added, such as solution of morphine 3 to 5 min., or heroin hydrochloride $\frac{1}{20}$ gr. The syrup of Virginian prune is also a useful vehicle in place of simple syrup.

It is important to bear in mind in all cases of pleurisy, whether of the kind now under consideration or of the next variety, that a large majority of instances are probably caused by the tubercle bacillus: consequently, after the acute symptoms have subsided the patient should be treated (in default of evidence to the contrary) as being a tuberculous subject, threatened with

tuberculosis of the lungs, and should lead an open-air life in the country or at the seaside for a suitable period of time, the longer the better, and certainly until complete restoration of strength and weight has occurred. Further, since the natural termination of an inflammatory condition of the pleura is adhesion of the two layers of the membrane, with a tendency to some limitation of the movements of the chest in the affected area, exercises, gentle at first, and subsequently increasing in vigour, should be devised to assist expansion of the lungs and free movement of the thoracic wall.

Pleurisy with Effusion, Sero-Fibrinous Pleurisy.—Acute cases may set in with severe pain, needing some of the measures for its relief described above. Pain usually ceases spontaneously when effusion occurs, but fever and constitutional disturbance may continue. The general management of the case is the same as in acute plastic pleurisy. The principal question which arises is as to the advisability of removing the fluid by aspiration. The general principles to bear in mind are that the presence of a small quantity of fluid in the pleural sac is not in itself of importance; large quantities, on the other hand, give rise to injurious pressure, with collapse of large parts of the lung, and after a time such a collapsed lung becomes bound down by adhesions and incapable of re-expansion. Again, when the pressure within the pleura is great, the veins and lymph channels in its walls are obliterated and thus disabled from acting normally in draining away the effused fluid. Relief of pressure by evacuation of some part of the effusion will lead to absorption of the remainder by these natural channels. The general rules of treatment, therefore, are to leave matters to nature as long as it is safe to do so, but to tap the chest when injurious pressure exists, or when so long a time has elapsed that there is danger of permanent collapse of the lung. The existence of harmful degrees of pressure is evinced by displacement of the heart and mediastinum, and by grave symptoms of cardiac or respiratory embarrassment (tachycardia, cyanosis, dyspnœa, pain in the chest or epigastrium). In some cases of "quiet" effusion in which the onset is gradual, displacement of the heart or the presence of physical signs, showing that the whole of one side of the chest is practically full of fluid, may be the only indications for tapping. Rough general rules for judging of the need for this operation are as follows: the chest should be tapped (1) when the fluid has been present for three weeks, and shows no signs of diminution; (2) when the upper level of dulness on the anterior wall of the chest reaches the second rib; (3) when both pleural cavities contain considerable quantities of fluid; (4) when symptoms of pressure as described above are observed; (5) when the fluid is purulent (see below, *Empyema*). On the other hand, the presence of fever, indicating that the inflammatory process causing the effusion is still active, is an indication to refrain from tapping as long as possible, as it is almost certain that the exudate will reaccumulate after the pressure has been reduced by tapping. While waiting for the fluid to subside naturally, it is advisable to apply iodine paint to the wall of the chest as a counter-irritant, and small doses of potassium iodide may be given, as in dry pleurisy, to stimulate absorption. The patient's bowels should be kept well opened, and if there be no special indication for fluid diet excess of liquid nourishment should be avoided, but there is no need to make the sufferer uncomfortable by keeping him actually short of drink. If tapping be decided on, the exact spot on the chest wall selected for puncture is immaterial, so long as one is chosen where there is definite dulness, pointing to the presence of a good depth of effusion, and care is taken to avoid injury to other parts (heart, diaphragm). The most convenient position for the patient during the operation is on his back, semi-recumbent, and supported on pillows: he should be brought conveniently near to the side of the bed, so that the operator may reach the point of puncture without difficulty, but on no account be turned on to the sound side for convenience in operating. A convenient point to select is the sixth intercostal space in the axillary region: this should be safely above the diaphragm, and well out of the way of the heart on the left side. The instrument usually employed is a trocar and cannula about $\frac{1}{10}$ inch in calibre, connected by a rubber tube to a bottle aspirator. Only a slight negative pressure need be induced in this at first, as the fluid flows readily: if the flow diminishes as the withdrawal proceeds, a rather greater degree of vacuum may be needed, but it should not be pushed to any high degree. The trocar and cannula are sterilised by boiling before use, and the patient's skin is prepared in the region selected by careful washing with soap and water, followed by application of ether or any other antiseptic preferred. The nail of the forefinger of the left hand, also sterilised, is then pressed into the intercostal space, and the point of the trocar quickly inserted above it. No anæsthetic is generally required, but for nervous patients the skin may be frozen with ether or ethyl chloride spray, or an injection of cocaine may be given. When the point of the instrument is felt to be free in the pleural cavity, the trocar is withdrawn as far as is necessary, and the cannula is placed in connection with the partially exhausted bottle by turning the tap on the corresponding limb of

the aspirator. If after a time the fluid ceases to flow readily, a few strokes of the exhaust-pump will increase the vacuum sufficiently to make it run. Sometimes, however, the orifice of the cannula becomes blocked with a plug of fibrin, and the flow ceases and cannot be restored by suction. In such a case the trocar may be cautiously pushed back along the cannula so as to dislodge the obstruction, care being taken not to injure the lung. If this device fails, and a fair amount of fluid has been withdrawn, it is best to suspend the operation and wait for a few days, to see if spontaneous absorption occurs now that the pressure has been somewhat reduced. Aspiration should in any case be suspended if the patient begin to suffer from pain in the chest, or from faintness or from cough. It is unnecessary to withdraw every drop of fluid present in the pleura, as any small quantity left will probably disappear spontaneously. An average amount to remove is probably about 2 pints, though more may be safely withdrawn in some instances. After the cannula is removed, the point of puncture may be covered with a collodion scab.

Two dangers may be associated with the process of aspiration of the chest, syncope and acute œdema of the lung. The risk of fainting may be avoided by operating with the patient semi-recumbent, and well supported by pillows, and by the administration of ½–1 oz. of brandy with a little water before puncture. Œdema of the lung is due to too rapid expansion of the tissue to fill up the space left by withdrawal of the fluid. It is unlikely to occur if the operation is suspended when any sign of coughing or pain in the chest is encountered. It has been suggested that air or nitrogen should be introduced into the evacuated pleural cavity and allowed to be slowly absorbed by the circulation, so that the expansion of the lung should be as gradual as possible. This somewhat complicated procedure is not often made use of, owing to the smallness of the risk. Should œdema of the lung, which is signalised by the expectoration of large quantities of frothy albuminous sputum, occur, it must be treated by administration of stimulants, such as brandy and ether, by venesection or wet cupping, and finally by inhalation of a few drops of amyl nitrite, which tends to diminish the blood supply to the lungs by dilating the systemic vessels.

The suggestion has been made to utilise some of the fluid withdrawn from the pleura for inoculation of the patient (auto-serotherapy). Such a procedure would be analogous to an injection of tuberculin in a tuberculous case, as the effused fluid doubtless contains the toxins of the bacilli. As, however, even when the pleural cavity is pretty fully aspirated, there is always a certain quantity of fluid left to be spontaneously absorbed, this will have the same effect as a hypodermic injection of the same fluid, while if only a small quantity is withdrawn by an exploring syringe, there is a constant absorption of the fluid from the chest, the method seems to have little theoretical justification, and has not come into general use.

Purulent Effusion, Empyema.—The presence of pus within the plural cavity is ascertained by puncture with an exploring needle, and the point of puncture should be carefully noted for guidance in the subsequent operation : indeed it is well to make sure of the presence of pus by this means immediately before undertaking the actual operation. Aspiration of a purulent collection is only to be employed in debilitated cases in whom administration of an anæsthetic or a serious operation is not thought justifiable, as for example in cases of empyema occurring in persons suffering from advanced consumption. It is said that empyema due to the pneumococcus may sometimes be cured by aspiration, but the more radical operation is even here the more certain means of cure, and as it is not itself dangerous, it should always be preferred. No rules can be laid down for the site of operation, as purulent collections may be met with at all parts of the pleural cavity or between the lobes of the lungs. A general anæsthetic is usually given, but the operation may be done under local anæsthesia. The skin is cleaned up in the usual way and an incision is made over the point where the pus has been localised. If the intercostal spaces are here wide, it may be sufficient to incise the pleura through the intercostal muscles, and insert a drainage-tube, but it is generally preferable to remove a portion of rib with view to free drainage. For this purpose, the incision, 2½ or 3 inches in length, is made over the rib, and is carried through the periosteum down to the bone. The periosteum is then stripped off with a raspatory, and a piece of bone about 1–1½ inches in length is removed with bone-forceps. The finger should be inserted to break down any adhesions forming loculations in the abscess cavity, and a drainage-tube is passed in so as to reach to the bottom of the cavity, being prevented from escaping into the chest by means of a collar of gutta-percha tissue, 1½ or 2 inches in width, which lies against the chest wall, and is kept in place by a dressing of absorbent antiseptic wool applied over it. The escape of pus is free at first, but gradually diminishes as the abscess cavity contracts and the lung re-expands. The drainage-tube is gradually shortened at successive daily dressings as this process takes place. In some cases (and this is occasionally seen after withdrawal of simple serous effusions also), the lung is so bound down by adhesions that it fails to expand after the operation, and a permanent

cavity remains between the chest wall and the lung, which continues to secrete pus. In such an event it may be necessary to remove considerable portions of several ribs over the cavity, and thus to let the wall of the thorax fall in and become adherent to the lung, as the only means of filling up the space (Estlander's operation). The procedure is one of considerable gravity, and should not be lightly undertaken. If a sinus persist after the drainage of an empyema, the use of a vaccine prepared from the organisms present may expedite its closure.

In cases in which an empyema has burst into the lung, and been expectorated, operative treatment should be deferred until time has elapsed to allow of spontaneous healing. If the spontaneous drainage is inadequate, surgical interference is still necessary.

Hydrothorax.—Passive effusion into the pleural cavities occurs in some cases of cardiac and renal dropsy. It is also met with in persons suffering from intrathoracic tumours, though here the effusion may be due to irritation of the pleura, rather than to mere pressure. In the former instances it is usually preferable to endeavour to treat the general waterlogged condition by tapping the legs or abdomen first, but the pleural fluid must be withdrawn directly if it is seriously impeding the action of the lungs. In cases of intrathoracic tumour, repeated puncture may be needed to relieve pressure, as indicated by dyspnœa and lividity. Apart from such urgent indications it is best to leave the effusion alone, as it is fairly sure to reaccumulate rapidly.

Pneumothorax.—The commonest cases of pneumothorax, those which occur in the course of pulmonary tuberculosis, are not in themselves dangerous—indeed, the induction of artificial pneumothorax is sometimes recommended as a form of treatment for this disease. No treatment is therefore required unless temporary collapse or dyspnœa occur, when stimulants, such as alcohol, ether, sal volatile or strychnine may be given, and oxygen may be inhaled if it is available. If pus appear in the pleural cavity as well (pyo-pneumothorax) the collection must be treated as was indicated above in the case of other empyemas in phthisis. When, however, pneumothorax occurs in a comparatively healthy person, as from traumatism or rupture of an emphysematous bulla, the initial symptoms are invariably severe, consisting of pain, shock, marked dyspnœa and even threatened suffocation. An injection of morphine is usually advisable when the patient is first seen, to quiet the excited action of the heart and relieve distress. Stimulants may be given at the same time. Should the pressure within the affected pleura continue to increase, owing to the existence of a valvular opening in the visceral pleura, it is necessary to puncture the chest wall with a trocar and cannula, as for pleural effusion, the cannula being left *in situ* after the trocar is withdrawn and connected with a length of rubber tubing opening beneath the surface of some boracic lotion or boiled saline solution, so as to prevent the possibility of any contamination of the pleural cavity when the positive pressure is relieved, and suction may take place through the tube owing to the movements of the chest. In case of urgency, if puncture in this way be impossible, a free incision may be made through an intercostal space. After puncture the side of the chest should be strapped with plaster to restrain its movements. The opening in the visceral pleura usually closes quickly, and the air effused into the pleural cavity is absorbed.

Diseases of the Mediastinum

Abscess in the Mediastinum.—If the presence of pus in the mediastinum can be recognised, the collection should, whenever possible, be evacuated by surgical measures. If the abscess point, simple incision and drainage may suffice, but it may be necessary to remove a portion of rib or to trephine the sternum. If the abscess has ruptured into a bronchus, no immediate treatment is advisable until sufficient time has elapsed to allow spontaneous healing to take place. If it breaks into the pleura, the treatment is that of empyema due to other causes.

Chronic Mediastino-Pericarditis.—This obscure disease is not amenable to direct treatment. Symptoms must be relieved as they occur, the œdema of the legs being reduced by incisions or by the insertion of Southey's tubes, the fluid in the pleural cavities tapped whenever it accumulates to an injurious extent, the heart's action maintained by digitalis and other suitable stimulants, and general venous engorgement treated, if necessary, by venesection. If there is any suspicion of syphilis, mercury and potassium iodide may be tried: they may in any case have some small effect as absorbents.

Mediastinal Tumours.—Only palliative treatment is here possible, though in growths secondary to cancer of the breast it is well to try the effect of thyreoid extract, while in cases of sarcoma it would be legitimate to advise the use of Coley's fluid, the risks involved, and the small prospect of positive result being first explained to the patient. The use of the X-rays has been recommended, but it is difficult to believe that they influence growths thus deeply seated. For spasmodic attacks of dyspnœa morphine may be given and oxygen may be inhaled: tracheotomy is clearly useless except in rare cases of laryngeal spasm. Pain may also call for morphine, if fomentations fail to give relief. Fluid accumulating in the pleuræ must be

withdrawn when it gives rise to dyspnœa, but tapping should be deferred as long as possible, as the fluid is sure to recur speedily.

Enlarged Mediastinal Glands, Tuberculous or Lymphadenomatous.—See *Treatment of Tuberculosis and Lymphadenoma.* W. C. B.

TREATMENT OF DISEASES OF THE CIRCULATORY SYSTEM

DISEASES OF THE PERICARDIUM

Pericarditis.—There are three chief problems to be considered: the treatment of cases which do not require surgical interference; of those which require paracentesis, or incision and drainage of the sac; and of those in which as a result of pericarditis or mediastino-pericarditis there supervenes a condition of cardiac asystole with persistent ascites and other evidences of profound cardiac failure.

Rheumatic Pericarditis.—Each of these problems may arise in connection with rheumatic pericarditis. As a rule medicinal measures only are needed, but in rare cases paracentesis or incision is required, and in exceptional cases cardiolysis has been undertaken for the treatment of extensive external pericardial adhesions.

1. Rheumatic pericarditis almost invariably points to a severe infection and forms one element in a general carditis.

The great enlargement of the cardiac dulness which is so frequent in the severe cases indicates far more often the occurrence of an acute cardiac dilatation than an extensive effusion. The practical importance of this is that paracentesis should not be undertaken unless the indications of extensive effusion are very definite.

The chief indications in the treatment are rest and skilful nursing; alleviation of pain and distress; protection of the heart from any undue strain; medicinal and other measures for the treatment of the rheumatism, and extreme care in the convalescence.

In the nursing of adult patients it is well to have a bed of a suitable height and breadth for easy lifting in case the patient should be helpless with rheumatic arthritis. The nurses should be strong as well as skilful, and must pay attention to the posture that is most comfortable to the patient. The diet should be fluid, and if there is difficulty in digesting milk this should be diluted, citrated or even peptonised. Stimulants in the form of brandy or whisky are indicated when there is lividity, sleeplessness or a rapid feeble pulse. The danger of dilatation of the stomach in the severe cardiac rheumatism of adults demands careful attention to detail in the amount of fluid nourishment. Severe vomiting, a dangerous symptom, may require treatment by rectal feeding and the resumption of food by the mouth in small quantities given at short intervals.

External applications for pain, which may be both pericardial and pleural, should be adapted to the physique of the patient. For delicate children warm applications, such as antiphlogistine are useful. For the more robust, particularly if there is considerable fever, ice-bags are frequently most useful. The details are as follows: Mark out the pericardial area and use if possible two bags, so that one can be at once substituted when the other is empty. Refill about every two hours. Put nothing between the bag and skin but a thin layer of butter muslin, and pack round the bag with cotton-wool. For fixing the bag a domette vest is useful with armholes and a third hole through which the neck of the bag is passed. The vest is fastened above by a tape passing round the neck, and below by a safety-pin to a binder. Hot-water bottles should be placed near the lower extremities. The pulse and temperature are taken when the bag is refilled. Every precaution must be taken to guard against and watch for any signs of collapse. If the right heart is failing the application of leeches to the precordium, or over the liver if that is enlarged and tender, is indicated. In adult cases it may be necessary if the forcible action of the right ventricle points to great embarrassment to bleed the patient, but the routine use of venesection is contra-indicated. Blisters are of doubtful value, and that a blood-stained or fibrino-plastic pericardial exudation should be influenced by them seems unlikely. They relieve pain, but the ice-bag, medicinal measures or leeches are more effectual.

The propriety of opening the pericardium and draining the sac in all cases of severe rheumatic pericarditis, with the object of getting rid of the infective agent and its poisons, has been suggested, but there are grave objections: in the risk of the operation, the difficulty of draining the cavity thoroughly, and above all in the fact that the infection is primarily deposited in the pericardial tissues. In the present state of our knowledge it seems then inadvisable.

Medicinal Treatment.—There is a decided difference of opinion upon this point. If it is thought that the salicylates are specific antidotes, then large doses are indicated for

these severe rheumatic infections; in fact the largest possible doses that are compatible with safety. On the other hand, if these drugs are not specific, such large doses are not indicated, seeing that even if prescribed with the greatest experience and care they are liable to cause peculiar toxic symptoms of their own. Among these are intense depression, nausea, vomiting, polyuria, tinnitus, delirium, coma, air-hunger and death. The writer believes these drugs relieve pain and lower the temperature, which latter is, however, rarely an urgent feature. Accordingly, he uses moderate doses for these purposes, and if the illness is critical on account of the severity of the cardiac inflammation prefers to avoid any risk from their depressant action. He would warn against the danger of giving large doses of salicylates to delicate, fragile rheumatic children with pericarditis, and the idiosyncrasy to these drugs which may be met with even in strong adults. Those who believe salicylates are specific, use for an adult such doses as 20 gr. of the sodium salt combined with 40 gr. of bicarbonate of sodium every two hours during the day and every four during the night.

For pain, nepenthe (♏ x for an adult) combined with salicylate of soda, or a hypodermic injection of morphia, may be required, and is usually better combined with atropine. For sleeplessness and delirium, usually associated with discomfort and general misery, opiates, and morphia in particular, may be required, but chloralamide, or the bromides, or a combination of these various soporifics may be sufficient in the milder cases, particularly if at the same time a small quantity of alcohol in the form of brandy is given at night. In some cases small *repeated* doses of nepenthe or Liquor Opii Sedativus produce a general peacefulness and bring much relief, but with others the same treatment will cause troublesome constipation and nausea.

The bowels should be regulated by an occasional dose of calomel and saline, and later by the use of mild aperients. Nausea and vomiting require prompt attention. Bismuth and soda after food may cut short this complication, or it may be necessary for a while to stop all food by the mouth. In some instances a very harassing cough distresses the patient, and for this heroin may be exceedingly useful, but morphia alone may bring relief. Little help is obtained from drugs acting directly upon the heart; and inflamed and poisoned as it is the action must be rapid and feeble. Strychnine may be helpful when the circulation is failing, but its routine use in the early stage does not seem purposeful. Digitalis, if combined with bromides or nepenthe, may, if it does not upset the digestion, calm the turbulence of its action in some degree and thus steady the circulation. Oxygen relieves the lividity and sense of oppression.

The value of anti-rheumatic or polyvalent anti-streptococcal sera is not established. Although the writer has seen recoveries with this treatment, he has been disappointed with their inefficiency in the serious cases when really put to the test. In the present state of our knowledge of vaccine therapy he would venture to impress the need for caution in their use, and would employ them for the chronic lingering subacute cases, beginning with a very small dose, 1 million. The treatment is only on trial at present, and it is a grave step to tamper with the natural processes of healing in any reckless fashion where such an organ as the heart is concerned.

2. Cases of pericarditis which require surgical interference are the result of various conditions. Among the most important are unusual cases of rheumatic pericarditis, hydropericardium in renal disease, some tuberculous cases, pyopericardium and malignant disease invading the pericardium. There are two methods open to us, paracentesis of the pericardium and incision and drainage of the sac. Improvements in local anæsthesia and the greater certainty of the procedure have led to the more frequent choice of deliberate incision. There are two conditions in which it seems contra-indicated. These are passive hydropericardium in renal disease, and pericardial effusion the result of new growths. In both instances we may get a clear idea of the nature of the fluid from a previous pleurisy, and in both illnesses it is advisable to choose the simpler undertaking of paracentesis. In pyopericardium, incision and drainage are imperative and in the rheumatic and tuberculous cases incision is advisable. We must remember that the diagnosis of extensive pericardial effusion is not, as a rule, easy and is sometimes exceedingly difficult. There are several reasons for this difficulty, and among them may be mentioned in particular the frequent absence of any definite pericardial friction in the suppurative cases. Complicating factors in the illnesses, such as left pleural effusions, empyemata or pneumonia and greatly dilated heart with or without some pericarditis, and a dilated heart surrounded by an inflamed and much thickened pericardium, may both give rise to extreme difficulty. The fluorescent screen is a decided assistance, but even this in the most skilful hands may lead us astray. The diagnosis must, then, rest upon a most careful study of the history, of the physical signs, and the radiographic results. Two questions have to be answered: Is there pericarditis? Is there effusion sufficient in quantity or of a nature to demand surgical interference?

Among the indications for paracentesis or incision on account of the quantity of the exudation are the physical signs of a large effusion coupled with such symptoms as orthopnœa, cyanosis or livid pallor, rapid respiration and a pulse which is of small volume, rapid and irregular. The indications for incision and drainage depend almost entirely upon the history of the conditions which led to the pericarditis.

Paracentesis pericardii is carried out with all the precautions for asepsis, and every preparation should be made to combat any sudden cardiac failure during the withdrawal of the fluid. When the effusion is large and the cardiac dulness extends beyond the cardiac impulse, the fifth space at the left limit of the dulness may be chosen. Some prefer the fourth or fifth intercostal space immediately to the left of the sternum. Others the same, but to the right of the sternum. Each case should be judged individually in deciding this point.

Pericardotomy is entirely a surgical procedure. Some surgeons prefer the incision over the fourth to the sixth costal cartilages on the left side. Others have approached the pericardium by opening from below through the diaphragm.

3. Cases of pericarditis in which asystole is developing from extensive external adhesion to the chest wall. These cases are usually treated on the lines laid down for chronic cardiac failure. Brauer's operation of cardiolysis or pericardial thoracolysis has, however, been of considerable service in some of them. The most favourable class of case is that in which the chief cause of cardiac failure is the passive adhesion. Those in which there is multiple serositis—that is, an adherent pericardium with recrudescences of inflammation in the pericardium or other serous membranes, are less hopeful. For such an operation to be successful, the heart wall must be powerful, as shown by the vigorous systolic retraction and rebound of the chest wall and by the disappearance of œdema and other signs of asystole when the patient rests in bed. The absence of a valvular lesion is an advantage, and the importance of any such lesion as far as possible estimated. The chest wall should be resistant, and for this reason the patient is usually adolescent or an adult. Von Beck and Wenckebach's cases were exceptions, but the pliant chest of childhood must make us consider the advisability of this operation even more carefully in the young than in the adult. Lastly, though the operation may be followed by remarkable improvement, it is not curative, and the recovery is only relative. Death may occur during the operation, although such an event has been very rarely recorded. A skilled anæsthetist is essential. The operation for a skilled surgeon is not difficult, and consists in turning up a curved flap exposing the third, fourth, and fifth left costal cartilages and ribs, and removing some three to four inches of each. Trotter, in the writer's case, did not remove the deep periosteum, and four years later there had been no re-formation of the bones. It is important not to damage the pleura. In a successful case, the œdema disappears, breathlessness decreases, the liver and spleen diminish in size and there is great physical benefit. Much attention must be given to the convalescence, and the writer's case has taken digitalis for four years; when left off on one occasion during an attack of bronchitis, œdema reappeared. This boy, now a young man, is over six feet high and lives a quiet, comfortable life, when before the operation œdema would show itself if he took the least walking exercise and had spread upward to the abdomen.

A distinction must be drawn between this operation and thoracostomy advocated by Morison for cases of aortic disease, with anginal pain and cardiac feebleness in spite of hypertrophy. Morison maintains that the heart is embarrassed by the thoracic cage. Here there is no question of freeing pericardial adhesions.

Convalescence after pericarditis is always slow, for the condition of the myocardium, particularly if it is additionally burdened by a concomitant endocarditis, is always one of weakness. The rheumatic cases are more tedious than the suppurative because of the general carditis produced by the infection. At least six months of supervision and cautious testing of the strength of the heart by increasing calls upon it are needed after severe pericarditis. If there are adhesions, improvement may never reach beyond some limited degree. The general principles of the treatment in convalescence are those described under myocardial affections. F. J. P.

DISEASES OF THE MYOCARDIUM AND ENDOCARDIUM

In few departments of medicine is careful and skilful treatment of so great importance as in that of cardiac disorders, and in few is it so well rewarded. While it is true, for example, that we cannot rectify the actual lesion in the case of a damaged valve or myocardium, it is none the less true that in a large proportion of cases it is possible, by the adoption of adequate therapeutic measures, to prolong life for many years, and in most cases to save patients from much suffering. Moreover, the work which has been done in recent years in the realm of cardiac disorders has resulted in a great advance in

regard to what can be accomplished in the large class of patients who are the subjects of auricular fibrillation, a condition which now can be recognised with certainty.

A. Methods of Treatment Applicable to any Cardiac Affection

In considering the treatment of any form of cardiac disorder, it is of great importance that we should first of all understand that the seat of heart failure is in the myocardium. Formerly the chief interest in cardiac affections was centred in the valves. Latterly it has been largely transferred to the heart muscle. It is the heart muscle which is the key to the situation; for it supplies the force which carries on the circulation.

Now, if this view of cardiac failure is correct, certain points of fundamental importance with regard to the management of any case of heart disease can readily be grasped. Our objects should be: (1) to do everything in our power to keep the myocardium in the highest possible state of efficiency; and (2) to avoid everything which may add to the gravity of the already existing lesion, or embarrass the damaged heart; (3) to treat cardiac failure when this is present; and (4) to treat symptoms and secondary results as they arise.

We should focus our attention on the heart muscle. On the one hand every factor which has an influence in strengthening it should be taken advantage of, while, on the other hand, everything which may throw a strain upon it (such as muscular or mental over-exertion, or supernormal blood pressure) should be considered carefully and in detail.

General Measures

Given a cardiac affection, whether valvular, myocardial, or arterial, one of the most unfortunate things we have to face is the fact that such a large proportion of patients endeavour to live beyond the limits of the heart's power. It is of supreme importance that this should be avoided. The patient should acquire the habit of always living within the limits of the heart's strength; there should be an absence of undue muscular or mental strain. It is not enough to regulate the amount of physical exertion; the importance of attending to the amount of mental work is not sufficiently realised. Severe mental exertion, and all forms of excitement, anxiety, worry and emotional strain should be prohibited, since these use up the heart force.

On the other hand, care should be taken not to restrict the pursuits of a patient unnecessarily; otherwise he is apt to become unduly nervous and introspective. While avoiding strain, the patient may be allowed to do as much physical or mental work as the strength of his heart will permit. With regard to the amount and kind of physical exertion which a patient may undertake without harmful effects, it is impossible to lay down hard-and-fast rules, for the reason that the constitution and temperament of different patients differ enormously. It is possible, however, to enunciate a great cardinal principle, which is of inestimable service. It is that any exertion which the patient may undergo should not be attended or followed by undue breathlessness, palpitation or fatigue, a sense of tightness across the chest, or precordial pain or distress. On the other hand, any exertion short of producing these is usually not harmful. Violent and sudden efforts, such as hurrying to catch a train or bus, walking quickly or bicycling uphill or against a wind, or lifting a heavy weight, should as far as possible be avoided. When exercise is taken, it should be entered upon gradually. But, while undue physical exertion should be avoided, a sufficient amount of exercise on the other hand is in every way desirable.

As a rule walking on the flat is preferable to hill-climbing, but in some cases a carefully regulated plan of hill-climbing is beneficial. Systematic exercises are sometimes particularly useful, provided they be judiciously and carefully employed and their effects watched.

When the cardiac affection is progressive, the amount of effort, physical and mental, should be proportionately reduced. It should be diminished in such a degree as not to produce symptoms of cardiac distress.

If the patient suffers from an unduly excitable nervous system, this should be carefully attended to, and for this the bromides are often extremely useful, but their long-continued use is not to be encouraged. The ammonium salt is less depressant than the potassium salt, and may be given in doses of 10–20 gr., three times a day after food. The bromides are also of value in sleeplessness, and in cases of angina pectoris in which there is excitability or irritability of the nervous system. It is difficult to exaggerate the importance of sleep, and its amount and character should invariably be inquired into, and if there is defect in either this should be energetically and skilfully treated on the lines laid down elsewhere.

A patient with an affection of the heart should lead a quiet and carefully regulated life. Excesses of all kinds should be rigorously avoided. Over-eating and the abuse of tea, coffee, alcohol and tobacco should be forbidden. It is better for the patient to be a

teetotaller. If, however, he has been accustomed to alcohol and deprivation makes him miserable, a strictly moderate amount of light wine or well-diluted spirit with meals may be allowed. Alcohol is often of great value in tiding over a time of danger. With regard to diet, the intake of highly nitrogenous food should be restricted, because it increases the resistance in the peripheral circulation. The three meals of the day should be evenly balanced. In most cases the daily amount of fluid should be somewhat restricted. The meals should be as dry as the patient will take them, a sufficient amount of fluid being taken between meals. The food should be nutritious, if for no other reason than that the heart should be well supplied with good blood; at the same time it should be easily assimilated, and unlikely to cause indigestion. A diet of carbohydrates is bulky, and is apt to cause flatulence and hyperchlorhydria, while a diet consisting of highly nitrogenous food increases the resistance in the peripheral circulation. Therefore, while the diet should be a carefully mixed one, the albuminous element should predominate. Anything which causes flatulent distension of the stomach or bowels should be avoided; since this, by direct pressure, embarrasses the heart, and is one of the commonest causes of palpitation. Articles of food which the patient knows by experience to cause indigestion should not be taken. In the opinion of most, a salt-free diet is of value as an aid in preventing senile changes in the arteries, and in the treatment of arterio-sclerosis and supernormal blood pressure. If dyspepsia is present, it should be attended to. The patient should be instructed to eat slowly and thoroughly to masticate the food, and when necessary the teeth should receive attention in order to allow of this. As the subjects of valvular disease are liable to malignant endocarditis particular attention should be paid to the teeth and gums, and constipation avoided or treated. In order to get an efficient removal of waste products, not only the bowels but the functions of the liver and kidneys, and the action of the skin, should be regulated.

It is important to try to prevent attacks of bronchitis and other affections of the lungs. It is very necessary also to guard against rheumatism in valvular disease, especially when of mitral origin, and particularly so in children or young adults. In all cases of heart disease, prophylactic measures should be adopted in regard to the risks of infection by influenza or other intercurrent diseases. The difficulty attending the diagnosis of rheumatic carditis and the importance of this condition are dealt with in the section relating to acute simple endocarditis. An attack of bronchitis or other affection of the lungs, rheumatism, influenza, or other febrile disease should be most carefully and energetically treated, and a sufficient amount of rest during convalescence should be enjoined. When exertion is again allowed, it should not be such as will produce any symptoms of cardiac distress; if it does the amount must be diminished. Any existing anæmia requires to be effectively treated by a plentiful supply of red meat, and iron with arsenic.

Patients who exhibit a gouty tendency should have their diet regulated, and take an occasional dose of blue pill followed by a saline aperient. Colchicum in combination with alkalies, or, if colchicum is not tolerated, a suitable substitute may be administered with advantage.

Where there is supernormal blood pressure, this should be regulated on the lines laid down elsewhere.

If there is reason to believe that heart disease is the result of syphilis, the iodides are frequently of value, and should be given in full doses, 15–20 gr., three times a day for some weeks; when the syphilitic infection is recent, mercury may be combined with iodides. In adults who are the subjects of heart disease a course of such tonics as iron, arsenic, phosphorus, or strychnine may be taken from time to time; while in children cod-liver oil, the syrup of phosphate of iron, or the syrup of iodide of iron are of special advantage.

Special Forms of Treatment

Rest.—It is difficult to exaggerate the importance of rest in the treatment of cardiac failure. I have no doubt that not infrequently improvement thought to be entirely due to some other therapeutic agency is, in reality, partly or wholly the result of rest. While rest is indicated in all cases of cardiac failure, it is of considerably greater value in cases without auricular fibrillation than in those with it; indeed, in the former group of cases, rest easily holds the first place among the therapeutic agencies at our disposal.

In determining the degree to which exertion should be curtailed, a cardinal principle, as has already been pointed out, is that the exertion which the patient indulges in should fall short of producing symptoms of cardiac distress. When there are indications of progressive exhaustion of the heart's strength, the amount of effort should be proportionately reduced, and in cardiac failure it may be necessary to recommend the patient to stay in bed. In the slighter degrees, it may be sufficient if he goes to bed for a couple of hours every afternoon or stays in bed one day a week. When heart failure is marked or extreme, as, for example, when orthopnœa and dropsy are present, the amount of exertion should be reduced to a minimum,

the patient being kept in bed for a period which may extend even to some months.

Diet.—In cases of cardiac failure unaccompanied by nausea and vomiting, light solids form the best diet, and, as a rule, agree better than fluid food. The daily amount of fluid taken, particularly at meal times, should be less than when there is an absence of cardiac failure. Specific instruction should invariably be given in regard to thorough mastication, and great care should be exercised to see that the patient does not take a larger quantity of food than he can comfortably digest. The food should be easily digestible, and those articles of food which are found not to agree with the digestive organs should be eliminated. When cardiac failure is extreme, the amount of food should be considerably restricted, and only very small quantities at a time, at fairly frequent intervals, should be allowed. Occasionally a milk diet or a modified Salisbury diet is best.

In the gastric crises, with vomiting, which sometimes accompany cardiac failure, milk is in the majority of cases the best food. Sodium citrate (15 gr. to each 10 oz.) may be added. If milk is not tolerated when taken in the usual way, peptonised milk, milk gruel, koumiss, or strong meat essences may be sipped, the patient not being allowed any solid food. If koumiss is given, no other food should be given at the same time. If one of the digitalis series of drugs is indicated for the general condition, and the patient is peculiarly intolerant of digitalis, strophanthus, squills, or one of the other substitutes may be tried. A brisk purge should be administered, and bismuth and hydrocyanic acid may be given. Iced champagne is sometimes useful, and counter-irritation over the epigastrium is occasionally of some help for the relief of vomiting. If, in spite of these measures, the vomiting still continues, all food and even water and drugs by the mouth should be stopped, and rectal feeding resorted to. The great advantage of rectal feeding with milk pancreatised for at least 24 hours in these cases, is not sufficiently realised. If dropsy is present, a salt-free diet is believed by most to be of value.

Systematic Exercises.—It has been pointed out that systematic exercises are sometimes particularly useful, provided they be judiciously and carefully employed and their effects watched. Graduated exercises are of special value in cases of slight cardiac failure due to the heart muscle being flabby and lacking in tone, as in fatty infiltration. It is essential that the myocardium should be fairly sound. Exercises are contra-indicated in acute affections of the heart, in considerable myocardial degeneration, in cases of severe cardiac failure, and in cases in which the heart failure is progressive. In my opinion simple movements are, certainly in most cases, better than the resistance exercises practised at Nauheim. Exercises may be indulged in even when the patient is confined to bed. They should stop short of producing any indications of cardiac distress.

Baths and Spa Treatment.—It is commonly known that immersion of the body in water may exercise a decided influence on the circulation. Some writers also believe that certain waters at Nauheim, on account of their ingredients, possess a specific therapeutic value in cardiac affections, but I am very sceptical with regard to this. Patients undoubtedly often derive great benefit from a stay at Nauheim and at similar spas, but this is almost certainly due to the change of air, the rest, the regular mode of life and exercise, the careful dieting, and other factors. Given the same conditions of life, similarly good results would be obtained anywhere.

Massage.—Massage is useful in many cases. It may be employed in cases in which the patient is confined to bed but in which absolute rest is not necessary, while, on the other hand, ordinary muscular exercise is not advisable. Massage and bandaging of the lower extremities are frequently of value in dropsy.

Drugs.—It is, unfortunately, in all probability true that the reputation of many drugs used in the treatment of cardiac affections does not rest upon trustworthy evidence. When a combination of various therapeutic agencies are employed, we should be careful to avoid crediting the administration of any drug with results which are in reality due to some other agency, more especially rest, or to the natural course of the malady.

A problem which has been notoriously a source of difficulty and perplexity to the clinician is the extraordinary difference in the results of the administration of digitalis or one of its allies in persons who are suffering from identically the same lesions, and complaining of precisely the same symptoms. As long as the drug has been in use for the treatment of cardiac affections it has been known that the results of its administration have been astonishingly variable; in some cases of cardiac failure it is of very great value, while in others it is ineffective. As an example of this, let us suppose three patients are suffering from precisely the same degree of cardiac failure and identical lesions, and the same dosage of digitalis is employed in each case. In one, perhaps, the results are extraordinarily good, the drug seems to act like a charm; in the second, the beneficial effect may be only moderate or slight; while in the third absolutely no good result at all can be detected. What is the cause of this variability? Is the drug capricious in its action or uncertain in its strength? It has been thought so. Or, is it due to some par-

ticular preparation being active while another preparation is inert? This has been thought by some; and for this reason special preparations have been prepared and advertised as being more uniformly certain in their action. These opinions have been proved to be wrong. Put briefly, the explanation of the extraordinary difference in the results of administration of digitalis or its allies is that the response to the drug differs according to the condition of the heart and character of the rhythm; those cases of cardiac failure which show wonderfully good results being, in the vast majority of instances, cases of auricular fibrillation.

The Digitalis Series of Drugs.—Of drugs used in cardiac affections digitalis is undoubtedly the best cardiac tonic. The commonly accepted special indications for giving digitalis are increased pulse-rate, say over eighty per minute, weakness of the contractile force of the heart muscle, cardiac dilatation, and anasarca; the cardinal indication being failure of tonicity. It is more generally useful in mitral than in aortic cases, especially in cases with scanty, high-coloured urine, and with dropsy. This is easily understood when it is remembered that auricular fibrillation is much more common in mitral lesions. The drug is often very useful when mitral regurgitation has become superadded to aortic disease. It is also useful in many cases of chronic myocarditis and fibroid degeneration, but the effects should be carefully watched in these cases. The question is often asked as to whether digitalis should be given in cases of aortic insufficiency. A supposed disadvantage is that slowing of the pulse, by prolonging diastole, allows more time for the distension of the left ventricle by the regurgitant current of blood. It should be pointed out, however, that slowing of the pulse may occur independently of digitalis. It is further urged that the use of the drug tends to cause sudden death in this affection. Patients have undoubtedly been known to die during its administration, but it does not necessarily follow that digitalis is responsible, for sudden death is apt to occur in aortic disease whether patients are taking the drug or not. In order to prove the contention, there should be no doubt that a relatively larger proportion of people suffering from aortic disease die when taking the drug than in the case of those in which it is not being used. In my opinion, there is no evidence to support this view. To be on the safe side, however, the drug should be given cautiously in this condition, and the patient should be kept in bed when considerable doses are being administered, while in those cases in which auricular fibrillation is not present the drug should be stopped as soon as the acute symptoms have gone.

Digitalis is, as a rule, contra-indicated in cases of undue slowness of the pulse. In these cases, if given at all, it should be cautiously administered. It should also be cautiously given or avoided altogether when there is a forcible apex-beat and bounding arteries. It is possible to do harm in cases of diminished conduction, though the drug is not necessarily contra-indicated. In these cases, care should be taken not to diminish conduction still further. Among the common beliefs, which are held without questioning by the profession at large, is the belief that the internal administration of digitalis increases the blood pressure in man by constricting the peripheral vessels. The result of this is that therapeutists are afraid of administering the drug in cases of cardiac failure in which there is degeneration of the arterial coats, for fear of rupture of their walls and consequent apoplexy, or where cardiac dilatation is associated with increased arterial tension from disease of the arterial coats and of the kidneys. Some try to get over the difficulty by prescribing along with digitalis some depressor, such as sodium nitrite or nitroglycerine, in order to dilate the vessels and so lessen the arterial tension. It should not be forgotten, however, that the effects of depressors are but transitory, while the rise in the peripheral resistance—if it is brought about by digitalis—is practically continuous. Others prefer to employ strophanthus in these cases, because of the prevailing view that it has little or no effect in constricting the vessels. I have shown from investigations [1] that, judged by the methods in use for observing the blood pressure clinically, the drug does not raise the blood pressure in man, and, therefore, there is no risk in administering it in cases of degeneration of the walls of the blood-vessels or of supernormal blood pressure.

But while the special indications for digitalis are increased pulse-rate, weakness of the contractile force of the heart muscle, dilatation, and dropsy, the results of its administration when these are present are very variable. The remarks which I am going to make on this subject are mainly based upon a series of investigations in which I was associated with Dr. James Mackenzie, Professor Cushny, and other workers at the Mount Vernon Hospital, dealing with the action of digitalis and some of its allies on the human heart.[2]

[1] See papers in the *British Medical Journal*, Sept. 21, 1912, and Sept. 13, 1913, and *Transactions* of the Seventeenth International Congress of Medicine.

[2] See a paper entitled "Recent Advances in Cardiac Therapeutics" in the *British Medical Journal* of Oct. 7, 1911, and another entitled "Recent Advances in the Diagnosis, Prognosis and Treatment of Heart Disease" in the *British Medical Journal* of March 8 1913.

These investigations showed that the response to the digitalis series of drugs differs according to the condition of the heart and character of the rhythm. Those cases of cardiac failure which show wonderfully good results are, in the vast majority of instances, cases of auricular fibrillation—whether the lesion be mitral, aortic, or myocardial—particularly when subsequent to acute rheumatism or chorea. If auricular fibrillation is present, and is accompanied by a rapid pulse, whether dropsy is present or not, digitalis is a therapeutic agency of wonderful potency; the results in the majority of cases being very good, and in some cases extraordinarily good. If that be so, it is of the utmost importance that we should be able to recognise auricular fibrillation clinically. It may be recognised with certainty by the following: (1) The pulse is completely irregular; it is an irregularly irregular pulse. The irregularity is more pronounced when the pulse is fast. When the pulse is slow, as, for example, when the patient is under the influence of digitalis, it may be necessary to take a tracing of the radial artery and to adopt careful measurements. (2) In mitral stenosis, a presystolic bruit, *due to auricular systole*, disappears with the onset of auricular fibrillation; if a diastolic bruit was present, it persists. A word of warning is necessary here. A murmur filling the whole space between the second and first sounds may be present in cases of rapid heart action, and the latter part of the murmur is not infrequently mistaken for a presystolic murmur due to the systole of the auricle. This mistake need not be made. The murmur is not crescendo in type, and on auscultating during one of the long pauses, or when the heart's rate becomes slow, a silence will be detected between the termination of the murmur and the first sound. (3) By means of the polygraph. In a tracing of the jugular vein there is an absence of the normal *a* wave; in other words, there is the ventricular form of venous pulse. The normal *a* wave cannot be present because the auricle does not contract. Instead of the *a* wave there may be multiple undulations. (4) By means of the electrocardiograph. In cases of auricular fibrillation, the administration of the drug is followed by a rapid fall in the pulse-rate and a concomitant improvement in the general symptoms. Two exceptions are: (1) Cases of cardiosclerosis in which the degenerative change is so widespread that little healthy muscle remains, and (2) cases in which there is pyrexia. When pyrexia is present, apparently the response to digitalis, if present at all, is as a rule very slight, whether auricular fibrillation is present or not.

With regard to dosage: as a rule improvement can be started after a time by small doses of 5 min. of the tincture three times a day, but in this case a much longer period is required than when large doses are employed, when the full effects are produced rapidly. The inference is, therefore, that it is better to begin with full doses and to go on with these doses until some physiological reaction is obtained; and then, if required, to continue the administration, but to regulate the amount until it is discovered what is the optimum dose in a given case. It is well to begin with a drachm of the tincture per day, or in urgent cases with even 1½ or 2 dr. per day, and to continue until there is nausea or vomiting, diarrhœa, headache, an unduly slow pulse, or what is called "coupling of the beats."

Usually a reaction is obtained within a week, sometimes in a few days. The drug should be stopped until these symptoms have passed away, which generally happens in a few days. As a rule the patient relapses. The indication then is to find out what dose suits him best—that is the dose sufficient to control the heart and maintain the slow action without producing toxic symptoms. It is a good plan to begin with half the original dose, and this can be increased or diminished according as the rate of the heart increases or diminishes. In this connexion, help may frequently be obtained from the patient himself, who is often able to say what quantity suits him best; in other words his own sensations are often a good guide, and should be taken into account as well as the pulse-rate. It may require weeks or even months of careful observation to find this optimum, and much perseverance will generally be required. There may be wide differences in the amount required in individual cases; this may be as small as a drachm per week, or as large as 45 min. per day. Having discovered this dose, in the great majority of cases it will be necessary for the patient to continue the drug for the remainder of his life. It may be necessary to diminish or increase the dose later on. Apparently the cumulative action is not nearly of such serious account as has been supposed; at the same time the pulse ought to be watched day by day. By this mode of treatment we can save many lives, and also bring comparative comfort to people who would otherwise be the subjects of much misery.

When auricular fibrillation is not accompanied by a rapid pulse, no marked result follows the administration of digitalis; the result is scarcely greater than in cases without auricular fibrillation. The improvement is slow, and it is often difficult to be certain how far the improvement may be due to the rest in bed and other measures adopted apart from the effect of the drug.

If the case is not one of auricular fibrilla-

tion, in exceptional cases fibrillation may occur during the administration of the drug; but, apart from these cases, and also cases of auricular flutter, as a rule, though not always, the beneficial results will be only moderate, or slight, or none at all. It is well to begin with large doses here also, and to continue until there is nausea or vomiting, diarrhœa, headache, an unduly slow pulse, extra-systoles or partial heart-block. We should be careful not to diminish conduction too far. Thus when extra-systoles or partial heart-block are produced the drug should be stopped or the dose reduced. If improvement in cases without auricular fibrillation does occur, it can usually be maintained without continuing the drug. Sometimes, however, it is advisable, after stopping the drug for a few days, to resume with smaller, sufficiently large, doses to maintain the slowed action and improvement. Here also other evidence of the patient's own sensations should be taken into account.

In giving digitalis there need be no fear of untoward results provided the indications previously mentioned are borne in mind. As long as the drug is not pushed after the first indications of its physiological action appear there is no danger. We should be cautious if the pulse is below seventy per minute. "Coupling of the beats" is a danger signal. Either the drug should be stopped for a few days or the dose diminished. It should be remembered that over-dosage may cause the patient much discomfort.

There is no evidence that any of the more recent preparations of the digitalis series are, generally speaking, superior to the tincture of digitalis for ordinary treatment. In some cases *strophanthus* and *squills*, while having the same action on the heart, seem to have less tendency to act on the digestive system. On the whole digitalis appears to be more certain in its effects than either strophanthus or squills. When it is unsuccessful as a rule the other drugs are of little value. Therefore digitalis is generally the most useful drug. The others should be regarded as substitutes for digitalis, and may be tried when a patient is peculiarly intolerant to the latter on account of the production of nausea or diarrhœa.

As a rule about twice as much tincture of strophanthus or of squills is required to produce the same effect as of digitalis. There is no special advantage in the various extractives obtained from digitalis. The tincture includes all the glucosides. With regard to the so-called alleged active principles of digitalis, it should be borne in mind that there is no pharmacological or clinical evidence that they are either pure substances, or that they are more reliable than different samples of the tincture. Possibly they are not so reliable. Nativelle's digitalin granules are a convenient form. Samples of tincture of digitalis supplied by firms of chemists of repute have proved wonderfully constant in strength. It is advisable, however, whenever possible, to get the tincture of guaranteed strength. The fresh infusion of digitalis is also reliable. The preparations of strophanthus on the market are not supposed to be nearly so trustworthy as those of digitalis. It was found that the active principles of digitalis, strophanthus and squills readily underwent decomposition when the tincture was diluted with water, and this was especially so in the case of strophanthus. For this reason, the tinctures should be dispensed as such or diluted only with alcoholic preparations, with directions to the patients to take them in water if necessary. Intravenous injections of strophanthin were employed by other workers at the Mount Vernon Hospital. These injections may be used in the most acute cases of cardiac failure, when it may be desirable to elicit a more rapid effect than is possible by the administration of tincture of digitalis, or one of its allies, by the mouth. Either two or three doses of $\frac{1}{250}$ of a grain at an interval of two hours, or a single dose of $\frac{1}{100}$ of a grain, may be administered. Whenever necessary, we can continue the administration of tincture of digitalis by the mouth. Some employ hypodermic injections of digalen or digitalin (the latter in doses of $\frac{1}{100}-\frac{1}{50}$ gr.) in cases of emergency, when a more rapid effect is required than is possible by administering tincture of digitalis by the mouth.

Caffeine has acquired a reputation in the treatment of cardiac affections, but this is, in the main, the result of its diuretic action, which is of great value. Apart from its diuretic action, caffeine may be tried when digitalis, strophanthus and squills have failed in cases of cardiac weakness and failure, particularly where there is no dilatation. It does not slow the pulse, and, therefore, bradycardia is no contra-indication to its use. *Theobromine* has a more constant and marked effect upon the kidneys than caffeine. *Agurin* or *theocin-sodium acetate* is of still greater value as a diuretic. *Diuretin* is also a good diuretic; it is more soluble than theobromine. Caffeine or theobromine may be used in conjunction with one of the digitalis group. Caffeine is apt to produce restlessness and sleeplessness. The others mentioned do not.

Strychnine has a great reputation in cases of cardiac failure when very rapid effects are required, but there is no absolutely reliable experimental or clinical evidence that in medicinal doses the drug has any effect upon the heart or blood-vessels. While this is so, many are of

opinion that the prevailing belief is supported by clinical evidence. The action of the drug is probably an indirect one as far as the heart is concerned, its essential action being that of a respiratory stimulant.

Diffusible stimulants (alcoholic, ammoniacal and ethereal) are of value in some cases of heart affections, particularly during temporary attacks of cardiac failure, and for the relief of urgent symptoms. Sometimes they may be given with advantage before there is decided cardiac failure.

Alcohol is supposed to be of greater value in the cardiac failure due to acute myocarditis than that associated with valvular disease. It is often a good thing to begin with a small quantity of wine with food. Ultimately, stimulants in larger quantities are required, and of these old brandy is the best. My custom is to begin with 2 or 3 oz. per day, gradually increasing the quantity as required and never going beyond 10 oz. daily, the amount being gradually reduced as the patient improves.

Atropine is supposed to paralyse the cardiac inhibitory terminations, and cases of heart-block have been recorded in which the writers have stated that in their opinion the drug was the means of increasing the ventricular rate. If this is so, it should be of service in Adams-Stokes' syndrome. One-hundredth of a grain may be given hypodermically, and repeated in half an hour if necessary. I am bound to say, however, that I have never seen any good result follow its administration in these cases.

Some believe that *iron* and *arsenic* are cardiac tonics, and, therefore, do not restrict the use of these drugs to cases of heart disease in which there is co-existing anæmia, but employ them in the early stages of cardiac failure. It is possible that arsenic is a nervine or muscular tonic. Sir William Broadbent believed that *phosphorus* was of more value than arsenic.

The *iodides* are frequently of value in gouty conditions, in supernormal blood pressure, in arterio-sclerosis, in aneurysm, in angina pectoris, and most of all when there is reason to believe that arterial or valvular disease is the result of syphilis. They may be taken for long periods. With regard to the effect of iodides upon high blood pressure, the results of some clinical investigations which I conducted at the Mount Vernon Hospital, showed that in no case was the administration of iodide of potassium, even when given in doses of 1 dr. three times a day, followed by a lowering of the blood pressure; yet in certain cases the drug seemed to be of value. In respect to arterio-sclerosis, while iodides may exert a beneficial influence in the earlier stages of the disease, it is practically certain that they are valueless in the later stages. When arterial, valvular, or myocardial disease is the result of syphilis, and, therefore, more frequently in aortic than in mitral disease the iodides have a specific value. In these cases they should be given in full doses (15–20 gr.) three times a day for some weeks. When the syphilitic infection is recent, *mercury* may, with advantage, be administered along with the iodides.

The *nitrites* may be given beneficially in cases of increased blood pressure or in angina pectoris—in the latter even if unattended with high pressure. Nitrite of sodium, erythrol tetranitrate, nitroglycerine and nitrite of amyl are most commonly employed.

Purgatives are of value in supernormal blood pressure, and when there are indications of distension of the right chambers of the heart and dropsy.

Diuretics should be given in cases in which the urine is scanty, especially if dropsy be present.

Oxygen.—This is sometimes of value in cases of cardiac failure. The chief indications for its use are dyspnœa, cyanosis and angina pectoris, particularly the two former. On the whole, I have been disappointed with the results of its administration, though occasionally substantial good has apparently attended its use. Leonard Hill has introduced a new method of giving it, by which the patient inhales almost pure oxygen.

Blood-letting.—This is of considerable value in a certain class of cases, and I am inclined to think that this mode of treatment is often not used when it might be employed with great advantage. It should be employed when there are indications of great distension of the right chambers of the heart—as, for example, severe dyspnœa, cyanosis, noticeable turgescence of the veins of the neck, and increased area of impairment of the percussion note to the right, especially when the radial pulse is small and weak, while, at the same time, there is forcible pulsation of the right ventricle in the epigastrium. As a rule, venesection should not be performed in aortic incompetence; in these cases it often does harm. My custom is to choose the median basilic vein, and to withdraw a good quantity of blood—occasionally even up to 20 or 30 oz.; sometimes, however, 6–10 oz. is sufficient. If venesection is not practicable, or is objected to by the patient or his friends, six to twelve leeches over the right ventricle or liver are good substitutes. When blood-letting is employed, it should be accompanied by dry diet and free purgation.

Treatment of Temporary, or more or less Permanent, Cardiac Failure.—In temporary cardiac failure, the amount of physical and mental effort should be reduced. If the indi-

cations of cardiac failure are slight, continuous rest in bed may not be necessary, although it is usually better to begin treatment by keeping the patient in bed for a short time. The amount of food should be restricted, and if necessary, efforts should be made to procure sleep. If the heart failure persists in spite of these, other remedies, including drugs, should be employed, and, if indicated, symptoms should be treated.

When the heart failure is extreme, as, for example, when orthopnœa and dropsy are present, absolute rest in bed is imperative. Further restriction of the amount of food, strict attention to the condition of the bowels, and, if necessary, the employment of therapeutic measures for procuring sleep, are indicated, while drugs appropriate to the condition should be employed until the requisite effects are obtained. Special symptoms should be treated as they arise.

In both temporary and more or less permanent cardiac failure the indications for, and the manner of employment of, each class of therapeutic measures have already been fully described.

Convalescence from severe cardiac failure is sometimes aided at first by gentle massage, and later by carefully regulated and gradually increasing exercises—at first passive, and later active—before the patient is allowed to get up. The movements should always stop short of producing breathlessness, fatigue, or other indications of cardiac distress, and should be followed by a period of absolute rest.

Treatment of Symptoms and Secondary Results. Rest, and other remedies previously described in detail should be employed in the treatment of symptoms and secondary results.

Sleeplessness.—The great importance of securing an abundance of sleep has been noted. Sleeplessness is often a troublesome, and may be a very grave, symptom. It should always be remembered that sleeplessness may be due to dyspnœa, and in these cases sometimes the patient is troubled with "night starts" as he is falling off to sleep; in these cases the dyspnœa should be treated on the lines laid down later. If necessary, hypnotics should be employed. I generally begin with the bromides; or, such mild hypnotics as trional, veronal, medinal, urethane, sulphonal or chloralamide may be tried. Chloralamide acts nearly as well as chloral hydrate in some, though by no means in all, cases, and is supposed to be safer. Paraldehyde is rather stronger; it is an extremely valuable drug in many cases, especially when there is dyspnœa. I have found a drachm of tincture of henbane, in a little hot brandy and water, sometimes succeed where these drugs were not successful. If these remedies fail, chloral hydrate may be tried. This drug has the reputation of being a dangerous remedy in heart diseases, especially in degeneration of the myocardium, but I have used it very extensively and have never found it so. It produces a natural sleep, and is especially useful when nocturnal dyspnœa and supernormal blood pressure are present. It should be avoided, however, where there is much bronchial secretion or œdema of the lungs. It may be given in 5–10 gr. doses by the mouth, gradually increasing to 15 or even 20 gr. if necessary, the dose repeated every two hours, the effects being carefully watched all the time.

If chloral fails, opium or morphia should be resorted to; these drugs are especially useful when there is accompanying restlessness and dyspnœa. The hypodermic administration of morphia is much more efficacious in cardiac failure than when given orally, and there are disadvantages attending the latter method. In regard to dosage, it is well to begin with very small doses, and gradually to increase these until relief is obtained, the effects being carefully watched. Cyanosis is not an absolute contra-indication to the administration of chloral, opium or morphia. Speaking generally, these should not be administered in cases in which there is much bronchial secretion or œdema of the lungs, or in Bright's disease; but in individual cases they may be tried if the first dose is extremely small, and the dosage is subsequently increased with the greatest caution. Further, when there is much bronchial secretion or œdema of the lungs, a sharp look-out should be kept to see if the drug increases this, when atropine or strychnine should be administered in combination with the morphia.

Gastro-intestinal Symptoms.—The treatment of these have been discussed under "diet."

Dyspnœa.—Shortness of breath is often a troublesome symptom, especially at night time. If gastric or intestinal flatulence be present, it should be attended to. Similarly, fluid in the abdomen may require to be withdrawn. If there are indications of congestion or œdema of the lungs, dry cupping should be employed. We should always be careful to exclude hydrothorax as a cause of dyspnœa; when present, paracentesis thoracis should be performed. Diffusible stimulants, such as ammonia and ether, and strychnine may be tried in dyspnœa. Strychnine undoubtedly has an action on the respiratory centre, and in patients who suffer from "night-starts" and nocturnal dyspnœa may be given in full doses in the evening. Venesection or leeching is sometimes of value in dyspnœa. For paroxysmal dyspnœa, vaso-dilators, such as the inhalation of amyl nitrite, or the internal administration of nitroglycerine, erythrol tetranitrate or sodium nitrite, are sometimes efficacious. When these various

measures fail, chloral may be employed, and if this is not successful opium or morphia. The contra-indications to the use of these drugs have already been noted under the head of sleeplessness.

Pain and Palpitation.—The possible causes of pain and palpitation should be carefully considered and adequately treated. Among the causes are gastric and intestinal dyspepsia, especially when attended with flatulence, toxic agents (such as tobacco and tea), hysteria, neurasthenia, anæmia and supernormal blood pressure. The last-named should be regulated by diet, exercise, mercury and saline purgatives, iodide of potassium and the administration of vaso-dilators. Although the effects of vaso-dilators are only temporary they are often serviceable in relieving pain and other symptoms associated with high blood pressure. Among others are amyl nitrite, nitroglycerine, erythrol tetranitrate and sodium nitrite. Iodide of potassium is not infrequently efficacious in cardialgia, even when not associated with supernormal blood pressure. When the pain is obviously due to overstrain or dilatation, rest is especially indicated. The bowels should always be carefully attended to. A belladonna plaster applied to the precordium is sometimes beneficial; while sometimes—especially in acute inflammatory conditions—a mustard leaf, blister, leeching, warm applications, or ice-bag affords relief. If these measures fail the bromides may be given a trial, and in the event of their not being successful it may be necessary to resort to opiates; nepenthe or tincture of opium in doses of 5–10 min. may be tried at first, the amount being subsequently increased as required. If the pain still continues, morphia may become necessary.

Cough.—The cause of the cough, *e. g.* œdema of the lungs or hydrothorax, should be treated. Warm drinks, or a large mustard and linseed poultice over the base of the lungs may be tried. A linctus may be necessary.

Hæmoptysis.—Hæmoptysis is only rarely a serious accompaniment of heart disease. Rest, a dose of calomel and saline purgatives are generally sufficient. A dose of morphia or heroin may be necessary. Venesection or leeching is advocated by some in severe cases.

Pulmonary Œdema.—The special treatment for this is dry cupping, and for acute pulmonary œdema prompt venesection is indicated.

Œdema.—The measures which are of particular value in the treatment of œdema are the restriction of the amount of daily fluid, free purgation, the administration of diuretics, and, in the opinion of many, a salt-free diet. A watery diarrhœa is not necessarily a contra-indication to purgation, because it is frequently due to passive congestion of the intestinal mucous membrane. I prefer a purgative in which some mercurial preparation forms a part, such as calomel and colocynth pill, followed by Epsom salts or some other saline in the morning. Pil. Hydrargyri, 3–5 gr., followed by a saline, may be given once or twice a week for a time. Of diuretics the best are digitalis, squills, caffeine, theobromine, agurin or theocin-sodium acetate, diuretin, scoparium and the acetate, citrate or bitartrate of potassium. With regard to digitalis, the infusion has a greater reputation than any other preparation of that drug in the treatment of dropsy, but I am not sure that this is warranted. Many people prefer a combination of drugs, and, in many cases, this method of treatment often appears to be most efficacious. Baillie's or Guy's pill, which consists of mercury, digitalis and squills, is a well-known combination. It is particularly useful in persistent dropsy due to cardiac failure; indeed, when given along with saline aperients it forms the most useful diuretic in many cases of œdema of heart disease. Among various prescriptions of this combination is the following—

℞ Pilulæ Hydrargyri
Pulveris Digitalis
Pulveris Scillæ
Extracti Hyoscyami aa gr. i
Ft. Pil.

One three times a day after meals.

Another good combination is 5 gr. of citrate of caffeine, 20 gr. of citrate of potash, and ½ oz. of infusion of digitalis.

If digitalis fails, one of the theobromine preparations, such as theocin sodium acetate, or agurin, each three times a day, may be added to it. Diuretin is a very valuable drug.

It is always best, when possible, to give mercury before beginning any of these drugs, as it appears to start the diuresis.

In early dropsy, a flannel bandage wrapped round the limbs is very useful, and this may be combined with massage. When the œdema does not disappear in spite of the measures mentioned, the mechanical removal of fluid should be considered. The means which may be employed are Southey's tubes, acupuncture and scarification. The first two are better than the third. Whatever method is employed strict aseptic precautions should be exercised. The dependent limbs and scrotum may be punctured, and then wrapped in sterilised dressings to drain. If ascites or pleural effusion does not yield to other treatment, and causes embarrassment, the fluid should be withdrawn. With regard to the former, Southey's tubes or tapping may be employed; in the case of the latter, tapping is necessary. When ascites and general ana-

sarca are both present, the one which is the more predominant should be treated first.

Faintness.—Among temporary measures for this complaint are plenty of fresh air, fanning, warmth to the feet, cold to the head and diffusible stimulants, such as ammonia and ether.

Extra-systoles.—Our first duty is to reassure the patient. This may be done with absolute confidence, since there is no evidence for supposing that extra-systoles in themselves—that is, without reference to the conditions with which they may be associated—are indicative either of an impaired heart or add to the gravity of any existing morbid condition. Any associated condition, such as excessive consumption of tea or coffee, or tobacco smoking, gastro-intestinal disturbances, supernormal blood pressure, or neurasthenia, should be treated. The general health should be attended to, and if cardiac failure is present it should be treated on the lines laid down elsewhere. Some hold the opinion that digitalis is of value for the irregularity itself. I have used the drug in many cases, and have never seen beneficial results to follow. The bromides are sometimes of value in modifying or masking the symptoms, especially in nervous subjects.

Tachycardia.—The treatment of tachycardia in heart disease has for the most part been dealt with in the general consideration of cardiac failure. The question of toxic agents (such as tea and tobacco), febrile states, neurasthenia and hysteria as possible causes of tachycardia should always be considered. The bromides, with belladonna, pushed to the limits of tolerance, appear to be of value in some cases of tachycardia.

Paroxysmal Tachycardia.—The results of treatment of this disorder are, in the vast majority of cases, very unsatisfactory. It is true that the paroxysm not infrequently ceases when various remedies are applied; thus, the bringing up of wind, the act of vomiting, the adoption of a certain posture, pressure upon the vagus, friction of the chest wall, and local applications in the form of an ice-bag, mustard leaves, or warmth to the precordia may be followed by relief. But it should be remembered that the nature of the disorder is to stop suddenly even without treatment. During the attack rest is indicated. As far as my observations have gone the remedy which offers most encouragement is strophanthin injected intravenously. The hypodermic injection of digitalin is not so hopeful. Failing the intravenous method, digitalis should be given by the mouth and pushed to the full physiological reaction. If there are indications of heart failure, such as dyspnœa, cyanosis, or dropsy, treatment on the lines laid down elsewhere should be adopted.

Between the attacks, the general condition, and whatever appears to be the exciting cause of the paroxysms, should be attended to. Any gastro-intestinal disorder should always be corrected. Bromides may be tried. In one case—and in one only—in my experience the continuous administration of digitalis proved effective.

Auricular Fibrillation.—In auricular fibrillation, whether there be mitral disease, aortic disease, or disease of the myocardium, if the ventricular rate is rapid, digitalis, or one of its allies, should be administered. The dosage, the choice of preparation, and the question of the great importance of the long-continued administration of the drug in most cases have been fully dealt with.

Auricular Flutter.—The term auricular flutter signifies a morbid condition in which, while the rhythm is normal, the contractions of the auricle are extremely rapid. When the attacks are transient, the treatment is that of paroxysmal tachycardia. When they are of longer duration or the condition has become permanently established, one of the digitalis series of drugs should be administered in large doses, and continued until the pulse-rate has decreased to about the normal, and the distressing symptoms have disappeared. After this, one of two plans may be adopted: (1) the dosage may be lessened, and afterwards the administration of the smallest dose necessary to control the ventricular rate continued in the hope that the flutter may cease; and (2) large doses may be continued, in the hope of inducing auricular fibrillation, after which the administration of the drug is discontinued for some days, in the hope of a return to the normal rhythm.

Bradycardia. Partial and Complete Heart-block. Adams-Stokes' Syndrome.—The cause of bradycardia should be attended to. When heart-block occurs during the course of infective diseases, rest in bed is indicated, and the cause, such as rheumatism, should be adequately treated. Persistent heart-block of mild degree requires no treatment in itself. But, as there is usually valvular or myocardial disease or both, it is of great importance that the patient should live strictly within the limits of the heart's strength. This is of still greater importance in cases of persistent heart-block of severe degree. Accordingly, the daily life of the patient should be most carefully regulated, and undue physical or mental strain should be scrupulously avoided. When there is reason to suspect that syphilis is the cause, appropriate and energetic anti-syphilitic treatment should be employed. When heart-block is associated with arterio-sclerosis, the amount of food, alcohol and exercise should be regulated, iodide of potassium should be tried, and if the blood pressure is high it should be regulated. If the patient is subject to fits, he should

be warned to avoid anything known to predispose to the attacks, and as far as possible he should be protected from the risks of falling. Unfortunately there is no drug which undoubtedly accelerates the ventricular rate of contraction, and, therefore, none is efficacious during an attack. Digitalis may be tried in cases of complete heart-block in which there is dropsy or some other indication for its use, for the drug does not slow the ventricle when that chamber is contracting independently of the auricle. Atropine may be given a trial, since cases of Adams-Stokes' syndrome have been recorded in which the writers have stated that, in their opinion, the drug was the means of increasing the pulse-rate and giving relief to the symptoms. $\frac{1}{100}$ gr. may be given hypodermically, and repeated in half an hour if necessary. I myself have never seen any good result follow its administration in this disease. Strychnine, oxygen and amyl nitrite have been administered, but there is no reason to suppose that they are of any value.

Pulsus Alternans.—As pulsus alternans is a sign of very great exhaustion of the heart muscle, complete and long-continued rest, both physical and mental, is urgently needed.

Supernormal Blood Pressure.—When supernormal blood pressure is present, attempts should be made to regulate it by the methods described in the article on *Diseases of the Arteries.*

B. Methods of Treatment Applicable to Individual Cardiac Affections

It should be clearly understood that the measures described as applicable to any cardiac affection in the main hold good in regard to individual cardiac affections. If this be taken for granted, much needless repetition will be saved in describing the treatment of individual disorders. The importance of rest whenever there are any indications of cardiac failure, the indications for, and the methods of, administering the digitalis series of drugs and other measures, as well as the treatment of symptoms, have already been fully described.

Acute Simple Endocarditis and Acute Myocarditis.—The management of a case of acute simple endocarditis or of acute myocarditis is of great importance, especially in regard to the future life of the patient. Acute rheumatism is by far the commonest cause, and it should be remembered that it is easy to overlook a rheumatic infection of the heart in childhood, since rheumatism in children presents many and important differences from the disease as it appears in adult life. In childhood articular inflammation is usually slight, and may even be entirely absent; while endocarditis and pericarditis are much more frequent, and should not be looked upon as complications but just as much part of the disease as is the affection of the joints. Subcutaneous nodules, the exudative erythemata, and purpura rheumatica are also more frequent manifestations of the rheumatic infection; while chorea also is common in connection with the rheumatism of childhood. While endocarditis may occur acutely in children as it does in adults, it more often occurs in a subacute and insidious form, and therefore its existence is frequently not known or suspected until the heart is examined.

When any child complains of pain in the joints, muscles, or tendinous structures, or of what are called "growing" pains; or has subcutaneous nodules on the tendons or round the joints, or subperiosteal nodules on the bones; or exhibits an erythematous eruption; or if there is a suspicion of chorea; or suffers from malaise and unexplained pyrexia; or complains of pain in the chest or shortness of breath; or presents marked pallor; he should be at once put to bed, and the heart examined carefully and systematically every day. Otherwise, a large proportion of the cases in which cardiac mischief occurs will be missed altogether.

When there is no doubt that the heart is affected by rheumatism, the indications for treatment are definite.

In the opinion of some, salicylates should be avoided when there is undoubted cardiac involvement, in the belief that when given for considerable periods they depress the heart and cause further dilatation. I do not share this view. Some prefer iodides to salicylates, given in full doses over considerable periods. A vaccine of the diplococcus of rheumatism is recommended by some, while cases have been recorded in which the administration of antistreptococcus serum, particularly in the prolonged or recurring cases, has apparently been attended by beneficial results. It may be given in 10 c.c. doses subcutaneously once a day for a week.

When the cause is other than rheumatism, it should be treated on the lines laid down elsewhere.

In all cases, whatever the cause, in which there is acute endocarditis or myocarditis, absolute rest in bed is indispensable. Its object is to assist the process of repair. At no stage in the management of a case should the heart be allowed to work up to the limit of its capacity. In the majority of cases absolute rest in bed is necessary for three months, and in some cases the period should be even longer. The patient should remain in the recumbent posture for at least a month after the fever has subsided. If tachycardia, or irregularity indicative of partial heart-block or of auricular

fibrillation, or if pulsus alternans be present, this period should be longer, even to three or four months. During the period that the patient is in the recumbent posture, he should on no account be allowed to sit upright in bed or to get out of bed for an action of the bowels. Afterwards, the amount of exertion should be most carefully graduated. At first, an extra pillow may be allowed. A few days later, the back may be slightly raised, and this may be gradually increased until the patient is moved on to a couch, in which position he should continue for a further period of three months. After the first two or three weeks of this period, very gentle massage may be allowed; and during the latter six weeks the massage may be increased, active movements may be indulged in, and the patient may be gradually allowed to sit up. Later, slight walking exercise may be permitted. For some months later great care should be exercised with regard to exertion, and the patient should be given rules as to the amount and kind of exercise; for, on the one hand, exercise may do much harm unless carefully regulated, while on the other hand it is of great value in moderation. If, during any of these stages, exertion is accompanied or followed by undue breathlessness, palpitation, sense of fatigue, precordial pain or distress, or increased frequency of pulse, the patient is doing too much and the amount of exertion should be reduced. Excitement and worry of every kind should be avoided. The diet should be light, small in bulk, yet highly nutritious and preferably solid. The daily amount of fluid taken by the mouth should be restricted to two pints of fluid per day. Saline infusions per rectum, or in grave cases intravenously, may be added. Strict attention should be paid to the bowels, preferably by mercury and salines.

In acute endocarditis, the internal administration of iodide of sodium in the later stages is employed by some. Dr. Caton recommended small blisters applied repeatedly to the precordium; I myself have been disappointed with the results. Mustard leaves may be used instead. Alcohol should not be given unless there is much exhaustion, dyspnœa, cyanosis, or an unduly rapid pulse. In these cases oxygen may also be employed. Alcohol is believed to be of particular value in the cardiac failure due to acute myocarditis. The best forms are good old brandy and champagne. The amount required of course varies with each individual case. It is well to begin with 2–3 oz. per diem, gradually increasing the quantity as required. For an ordinary severe case I generally average 6–8 oz. of brandy in the twenty-four hours. I never go beyond 10 oz. per diem. The amount should be gradually decreased as the patient improves. Other diffusible stimulants, such as ether and ammonia, may be employed. Camphor and tincture of musk are used a good deal on the Continent of Europe. Strychnine has a great reputation in the treatment of cardiac failure due to acute myocarditis. It may be tried when there is great exhaustion. In the writer's opinion, it is much better given hypodermically. In severe cases it may be given up to $\frac{1}{60}$ gr., or even $\frac{1}{30}$ gr., every two hours. The results of the administration of the digitalis series of drugs are, as a rule, extremely disappointing. The response is usually very slight, if at all, whether auricular fibrillation is present or not. In suitable circumstances quinine may be administered; and if anæmia is present iron and arsenic may be prescribed. When the blood pressure is very low, 5 min. of a 1 in 1000 solution of suprarenal extract, or pituitary (infundibular) extract, may be administered by the mouth. The treatment of symptoms has, in the main, been dealt with previously.

For precordial pain or distress, a hot linseed poultice may be applied to the precordium, and if this fails the continuous application of an ice-bag may be tried. Dover's powder (10–15 gr.), or, if necessary, morphia may be given by the mouth. In the less acute pain a fly blister is not infrequently efficacious. During convalescence extreme care should be taken not to allow the patient to do too much.

Malignant Endocarditis. — Needless to say, absolute rest in bed is *the first* essential, and exposure to the open air is of value. The teeth should be carefully attended to; if pyorrhœa alveolaris is present, it should be treated. The diet should be fluid and liberal in amount, and the bowels carefully regulated. Many drugs have been employed in the treatment of this disease, among them being quinine, the sulphocarbolates, carbolic acid, mercury, arsenic, formalin, and the organic preparations of silver (such as protargol). Quinine is probably of value in lowering the temperature. In those cases in which leucocytosis is absent or slight, nuclein may be given by the mouth, subcutaneously, or even intravenously. If given subcutaneously the dose should be 5–15 min. of a 10 per cent. solution once a day. Silver salts may be given in combination with nuclein.

Within recent years specific measures, in the form of vaccines and antisera, have been extensively employed in the treatment of this disease, but the results, on the whole, have not been encouraging. Some combine the two methods. Better results are obtained from the patient's own micro-organisms than from stock vaccines. An attempt should be made to isolate any organism which may be present in the blood, and if successful a vaccine should be

prepared. The question of dosage and the determination of the proper intervals between successive doses is difficult. Formerly it was thought that frequent estimations of the opsonic index afforded a good guide. We now know that this is not the case, if for no other reason than the fact that in malignant endocarditis there is a constant fluctuation of the index. The clinical symptoms and temperature, however, are of service, and should be carefully noted. It is most important to avoid too large and too frequent dosage. We should begin with a small dose, and proceed very cautiously, both in regard to an increase of dose and in lessening intervals between the doses. If any dose is followed by pain in the limbs, headache, increase in the severity of symptoms, or rise of temperature, it is either too large or the period of time that has elapsed since the preceding dose has not been sufficiently long. In such a contingency, the next dose, therefore, should be a smaller one (perhaps a half or even less), and it should not be increased for some little time, and, as a rule, at a longer interval. As an example of dosage and spacing of the doses, we may try 2–5 millions streptococci or 50–100 millions staphylococci to begin with, administering a second dose after an interval of 3–5 days, and carefully watching the effects. During the time that the vaccine is being prepared from the patient's own micro-organism a stock preparation of the micro-organism may be employed. When streptococci are found, anti-streptococcus serum (univalent or polyvalent) may be employed. Ten c.c. may be given subcutaneously, or 15 c.c., per rectum, daily for three or four days, after which there should be an interval of several days. If the administration is followed by an increase of symptoms or rise of temperature, small doses, such as $2\frac{1}{2}$ c.c., should be substituted. When the condition is due to the pneumococcus, Merck's or Pane's antipneumococcus serum may be tried in full doses.

The daily administration of normal horse serum, either subcutaneously or intravenously, has recently been well spoken of.

In cases with an unduly rapid pulse, great exhaustion and cardiac dilatation, alcoholic stimulants and strychnine may be employed. The best method of reducing the temperature is tepid sponging of the body; of drugs, the best is quinine. Other symptoms should be treated on the lines laid down elsewhere.

Hypertrophy.—This in itself does not need treatment. It is always advisable, however, to consider the cause, and, in some cases, as for example, when chronic Bright's disease, supernormal blood pressure, or arterio-sclerosis is present, it should be suitably treated. In order to provide a good supply of food to the heart muscle, we should see that the patient gets plenty of fresh air and an adequate supply of nutritious and easily digestible food, and if dyspepsia or anæmia is present it should be attended to. Undue physical or mental strain should be avoided. If cardiac failure supervenes, it should be treated as described elsewhere.

Dilatation. Mitral Insufficiency apart from Structural Alteration of the Value.—Dilatation of the left ventricle apart from structural alteration of the value may cause mitral insufficiency. The cause, such as chronic Bright's disease, supernormal blood pressure, arterio-sclerosis, aortic disease, undue physical strain, alcoholism, bacterial poisoning, influenza or anæmia, should be attended to. Rest is imperative. Other general measures, as well as special forms of treatment, and the treatment of symptoms have been described. If auricular fibrillation is present, in association with a rapid pulse, digitalis is clearly indicated. When the dilatation is due to poisoning, digitalis appears to be unavailing.

Chronic Myocarditis. Myocardial Degeneration.—In either condition it is of great importance that the patient should curtail his physical and mental activities so as not in any way to exceed the limited strength of the heart. The daily life of the patient should be gone into with great care and in detail. Carefully regulated exercise in the fresh air is useful, but violent and sudden efforts should be strictly forbidden. Scrupulous care, however, is necessary in this direction. The amount and kind of exertion should be adapted to each individual according to the strength of the heart muscle. Such exercise as walking against a wind, and cycling uphill are contra-indicated; on the other hand, quiet walking on the level, or even slow walking up an incline, quiet cycling, croquet, and even riding or golf may usually be allowed, excepting in advanced cases. Exertion should stop short of producing undue breathlessness, palpitation or fatigue, a sense of tightness across the chest, or precordial pain or distress. If these precautions are not taken there is real danger. Even when there are no indications of cardiac failure, periods of complete rest are often useful. High altitudes are better avoided. Only warm bathing should be allowed. The clothing should be warm. Particular care should be taken in regard to diet; it should be most carefully regulated on the lines previously laid down.

Gastric and intestinal dyspepsia, especially with flatulence, should be avoided, or treated when present. What fluid is taken with meals should be taken *at the end of* meals. Overloading of the stomach should be avoided. Rest before and after food, and in the after-

noon, should be enjoined. The state of the bowels should be carefully attended to. In these cases, it is sometimes of advantage to diminish the body weight. If there is supernormal blood pressure it should be regulated by the methods described elsewhere. If anæmia is the cause or an accompaniment of the condition, it should be adequately treated.

When there are indications of cardiac failure, rest, proportionate to the degree of failure present, is imperative; other therapeutic measures, also, as previously described, should be adopted. The indications for one of the digitalis series of drugs have already been pointed out. Even in cases of auricular fibrillation in association with a rapid pulse, as a rule the response is not so good as in heart disease following rheumatism. Such complications as angina pectoris may require to be treated.

Fatty Infiltration.—Treatment consists mainly in dieting, systematic elimination and abundance of fresh air, while carefully regulated exercise and other measures which have for their object the reduction of bodily fat should also be employed. The diet should be strictly moderate in amount, and sugars and starches, especially bread and root vegetables, should be proportionally diminished; the diet, therefore, must be mainly nitrogenous. The food should be eaten slowly and thoroughly masticated. The amount of fluid with meals should be restricted, and what is taken should be taken at the end of the meal, while, on the other hand, a considerable quantity of fluid between meals is advisable. It is better to avoid alcohol altogether, but, if this is not possible, brandy or whisky, well diluted, Moselle, or claret are much preferable to malt liquors, Burgundy, port and champagne.

Regulated exercise in the open air, such as walking, riding, golfing and cycling, are valuable. Exercise indoors, as, for example, the use of dumb-bells, is of benefit as adjuncts. Graduated exercises are of special value in cases of slight failure due to fatty infiltration. In my opinion the simple forms of movements are, certainly in the majority of cases, better than the resistance exercises practised at Nauheim. These movements may be indulged in even when the patient is confined to bed. With regard to all forms of exertion, care should be taken that it is at first limited in amount and only gradually increased, while it should stop short of producing any indications of cardiac distress. Systematic elimination by means of purgatives, Turkish baths, and a visit to a spa, such as Harrogate, is sometimes useful.

Valvular Disease.—If there are no indications of cardiac failure no direct treatment is necessary. But explicit and detailed instructions in regard to the manner of life he should lead (as fully described under general measures) should invariably be given to the patient. The importance of always living within the limits of the heart's strength and the avoidance of sudden and violent effort is of especial importance in aortic disease. The teeth, gums and bowels should invariably be attended to, in order to diminish the risk of malignant endocarditis. In mitral disease due to structural disease of the valve, the patient is liable to attacks of bronchitis and bronchopneumonia; while in both mitral and aortic disease in children and young adults there is the liability to subacute and acute rheumatic attacks. Preventive measures in regard to these should be adopted. When, in valvular disease, there are indications of cardiac failure, such as dyspnœa, it is imperative that the work of the heart should be lessened by rest. If the cardiac failure is slight in degree, continuous rest in bed is often not necessary; it is often advisable, however, to begin treatment by keeping the patient in bed for a little time. Other measures which may be adopted, as well as the indications for the administration of digitalis, have been dealt with already. In mitral disease the tendency is for the occurrence of cardiac failure, while in aortic disease the patient is especially liable to pain in the precordium and to cerebral symptoms. The treatment of these has already been described.

Congenital Heart Disease. — The general measures previously laid down are applicable also to this affection. It is particularly important that the child should be kept warm, and it is imperative that careful and detailed measures should be adopted for the prevention of bronchitis. When cardiac failure supervenes, it should be treated on the lines previously described.

Angina Pectoris. — The treatment of true angina pectoris resolves itself into two parts: (1) that which aims at preventing the recurrence of the paroxysm; and (2) that which has the object of relieving the paroxysm.

With regard to the first of these, we should try to improve the general health, more especially the circulatory and nervous system; and since the condition occurs usually in association with exhaustion of the heart muscles, a cardinal indication is to try and remedy this exhaustion and to prevent its recurrence. In this connection, it is advisable first of all to review the etiology of angina pectoris, and to endeavour to find out the cause of this exhaustion, and for this purpose it may be necessary to inquire in detail into the past and present life of the patient. In some cases the clear indication is to enjoin rest, proportionate to the degree of exhaustion. With this object in view, it may be necessary to order complete

rest in bed for some time, and even to give sedatives, such as chloral or opium. Morphine is in most of these cases more useful than opium itself. After a period of rest explicit instructions should be given to the patient that in future he should live within the limits of the heart's strength. He should avoid any exertion which produces undue breathlessness, palpitation, or fatigue, as well as hurry, sudden effort, walking or hurrying against a cold wind, especially after a meal. Cold sheets at night should also be avoided, and a cold bath in the morning should be prohibited. The nervous system may be a factor in the production of angina pectoris, and when there is reason to believe that this is the case appropriate measures should be employed. When the patient has suffered from a period of mental strain or sleeplessness, and, indeed, whenever there is any excitability or irritability of the nervous system, the administration of bromide of ammonium, in doses of 10–20 gr. three times a day is often of great value. Emotional excitement, gastro-intestinal dyspepsia—particularly that form which is accompanied by flatulent distension—constipation, and all other possible exciting causes of the attacks should be carefully avoided or treated when present. Over-indulgence in diet, alcohol and tobacco should be avoided. Flannel should be worn next to the skin both summer and winter. When there is reason to believe that syphilis is the cause, appropriate and energetic anti-syphilitic treatment should be employed. Similarly, if high tension is present this should be treated on the lines laid down elsewhere. Indeed, we should review the whole of the causes of angina pectoris, predisposing and exciting, with a view to treatment. Of drugs which may be given with the hope of preventing an attack, the most hopeful are iodide of potassium and nitroglycerine. The former is probably in most respects the best, and is particularly indicated when arteriosclerosis is present, more especially if there is a history of syphilis. In some cases 5 gr. doses are sufficient, while in others the drug should be pushed. Nitroglycerine may be given in the form of tablets or the pharmacopœial solution; one-hundredth of a grain be given three or four times a day, and gradually increased to $\frac{1}{20}$ gr. or even $\frac{1}{10}$ gr. Either drug should be given intermittently for two or three weeks at a time, while in some cases it is good to alternate them. Sodium nitrite, erythrol tetranitrate, mannitol nitrate and nitrite of potash are other drugs which may be employed. Taken altogether, the nitrites are not so valuable as the iodides.

For the paroxysm, the most efficacious remedy in most cases is the inhalation of nitrite of amyl; the action of the drug is almost immediate and the relief is usually complete, this being particularly so in cases of widespread arterial constriction. In many cases, however, it is absolutely useless. It is best administered in the form of the glass capsules or perles, which the patient should carry about with him. Each contains from 3 to 5 min., and one should be crushed between the folds of a handkerchief and inhaled freely. The dose may have to be repeated. A similar effect may be obtained by nitroglycerine, but its action is not so rapid, while its effect is more prolonged. It may be given in the 1 per cent. solution of trinitrin, beginning with 1 and increasing if necessary to 5 min. doses, in a little water; or, the patient may nibble one or more tablets until the pain disappears. If there be flatulent distension, a draught of carminative mixture, or if this be not available some very hot water with a little essence of peppermint or brandy, sipped slowly, may be given with the amyl inhalation or the nitroglycerine drops. In cases in which there is pronounced heart failure, brandy or ether, preferably the latter, in doses of 20–60 min., in which 1–2 min. of trinitrin (1 per cent. solution) may be dissolved, may be injected subcutaneously. Erythrol tetranitrate and sodium nitrite are not so suitable for these attacks. If the drugs enumerated fail, chloral by the mouth, hypodermic injections of morphia, or inhalations of chloroform should be employed. Twenty grains of chloral hydrate may be tried. As a rule it is necessary to give morphia in larger doses ($\frac{1}{4}-\frac{1}{3}$ gr.) than in other disorders. A $\frac{1}{50}$ gr. of nitroglycerine may be combined with the morphine. The nitrites and chloroform are not of such value in cases in which there is an absence of decided arterial spasm as in cases in which it is present. Where there is cyanosis or asthma, oxygen inhalations may be tried, particularly in those cases in which morphia is found necessary. If the drugs enumerated are not at hand, hot drinks, water containing whisky, or brandy, capsicum, spirits of chloroform, or a carminative mixture, may do good by the relief of flatulence.

ATHLETIC OVERSTRAIN OF THE HEART

Overwork of the heart in an athletic boy usually first affects the left side; and in an athletic young man, the right side. The features of the attack vary with the part involved and the degree of overwork; when the right side is concerned, the earliest stage is a tumultuous state of inefficiency, while the same stage of a left-sided case is an intermittent disturbance passing off with exercise and reappearing with rest. Loss of tone is marked in both cases. To mention some of the features:

breathlessness, shallow respirations, deep coloration of the face, aching and "tightness" of the chest, increased pulse frequency *in all positions* and high blood pressure irrespective of posture point to right-sided trouble. Later there may be a diffuse, "wavy" impulse and epigastric pulsation. On the other hand, a sense of great insecurity, with loss of power, nausea, chilliness, breathlessness *on exertion*, fall of blood pressure and of pulse-rate to a subnormal level on resting, and a leaden hue point to the left side. When both sides are affected there still remains the stamp of one side or the other with fresh features, *e. g.* tenderness, especially of the "apex," spacing of the heart sounds amounting at times to something very like a tic-tac rhythm with a rise in pitch and a fall in volume, loss of tone which persists for weeks instead of for days, crepidations at the base, more often of the right side. The heart has no power of adapting itself to either work or position until the pressure is lowered. This degree of overwork is not reached *suddenly* in a healthy athlete.

The degree of enlargement is of no great use as evidence of overwork for two reasons. We do not know the size of the heart due to hypertrophy in any particular case, and the increase in size may be apparently no greater than that seen in the same heart at the end of an ordinary day which has included some very vigorous exercise.

The ability to take hard exercise rapidly decreases in athletic boys and men *who have allowed themselves to become soft*. They are apt to forget this and suddenly determine to go to the help of a team in a "tight place" with very evil results to themselves at times. In extreme cases their symptoms and signs are: blueness, breathlessness, a running pulse with rapping heart sounds, dilatation of the auricle which can be percussed out, engorgement of the veins. Percussion of the ventricle at this stage shows little or nothing because of the jerky breathing with distension of the chest.

At a later time one can satisfy oneself that the cardiac dullness is increased over the ventricle much more than it ever seems to be in the healthy athlete, however overworked his heart may be. (Acute dilatation in a *healthy* young athlete of the whole heart has never come my way; possibly I have missed it. Such a patient's margin of safety is stupendous.) All degrees of this are seen between one extreme marked by breathlessness and perhaps an occasional thud of the heart with passing increase of breathlessness and the other rarer extreme just described. The most troublesome result to the patient is irritability of the heart not by any means purely psychical. It is a real inefficiency, with a definitely greater and widespread consciousness of the beats of the heart, regular and irregular. The consciousness can be favourably influenced by valerian and the mixed bromides of sodium and ammonium, and he sleeps better, but there remains difficulty in regaining the reserve power of the muscle. I do not desire to be dogmatic, so I give my evidence, which is this: I have seen over 300 irritable hearts in fifteen years, not all of home manufacture, and not one of them has got better while the patient was allowed to take exercise, which, while in health, he would have looked on as trivial. The most important factor in treatment is rest, and *enough of it*. The patient must be put to bed, and if there is a high blood pressure it should be reduced; for this purpose diuretin 15 gr. every two or three hours is sufficient and does not depress the heart. The first sign of recovery is that the circulatory system "breaks away" from the influence of the drug as shown by a rise in pressure and in pulse frequency.

When there is no longer increasing pulse frequency I have generally found the heart fit for carefully graduated passive exercises, progressing to sitting up in bed and so on. This usually occurs after three days of rest in a right-side affection. Any sign of irritability or weariness, such as extra systoles or the dropping of a beat, followed by a thud or a succession of weak beats is an indication that the work of the heart should be lessened again.

Another method which is often beneficial is the full-length hot bath. The room should be well ventilated and the patient kept in the bath at as high a temperature as he can stand till he begins to sweat. He should then be *lifted* out and *carried* to a *warm* bed. The room should be darkened and sleep promoted by a draught containing, *e. g.* chloral hydrate 10–20 gr., sodium bromide 10 gr., and ammon. bromide 10 gr. After a sleep the patient may wake up quite comfortable and may have no return of symptoms. This treatment is specially suitable for patients who are keenly sensible of a "bumping" of the heart. As the blood pressure falls the other symptoms tend to subside gradually. The after-treatment of these right-sided cases involves careful restriction of food and exercise so that there is no risk of cardiac overwork for a period of three months. Cause: Often deficient chest movement.

When the left side is affected, rest in bed is also necessary. Pulse-rate and blood pressure then fall below normal, sometimes in one or two hours. In one such case I observed a pulse-rate of 39 and a blood pressure of 90 mm. (Riva-Rocci). On attempting to sit up the pulse-rate increased to 130, while the blood pressure only rose to 110 mm. The most useful drug at this stage seems to be strophanthus. While waiting for it to act a

diffusible stimulant should be at hand in case of respiratory discomfort which may come on when the patient is first put at rest. These hearts respond more readily to drugs of the digitalis series than do diseased hearts. Strophanthus is well borne by the stomach, but digitalis should be substituted as soon as the heart begins to settle down to a more regular rhythm, and the risk of vomiting is past. It produces its finest effects when given regularly day after day in as large doses as can be taken without exciting nausea or subjective consciousness of the heart's action. Reduction in the amount taken should be brought about by reducing the number of successive days in the week on which the drug is given, and not by reducing the dose or the number of doses a day. *Gradated* exercise should be resumed as soon as the heart has steadied. The earliest forms of exercise should be gone through while *lying* on the bed, the latest on a level road escorted by a vehicle. The test of the heart's condition is its increase in speed of beat: when this is more than 10 to 15 per cent. two minutes after coming to rest in a sitting position, it is being asked to do too much. I am assuming that the blood pressure does not fall when the heart quickens, if it does the state of affairs is not merely overwork. To allow of complete recovery very gradual increase of exercise, abstention from tobacco and from all stimulating foods, avoidance of all forms of excitement, and in some cases even of any forms of *keen* interest are necessary.

The need for immediate treatment in the severe degree of overwork and enfeeblement seen in the unfit is met by venesection and the withdrawal of 15 oz. of blood coupled with the use of a vaso-dilator to prevent any subsequent rise of blood pressure. When walking on the level begins, a wary eye must be kept on the pulse at the time of exercise, and until the patient can walk a mile without persistent quickening of the pulse, every walk should end where his doctor can see him.

In this way much irritability and its attendant limitation of usefulness, as well as the enlarged inefficient heart which is only good for a regular procession of easy days, are avoided.

These patients are helped by anything which improves the condition of the blood, *e. g.* arsenic and iron, the former drug being of the greater importance; hæmoglobin and glycerophosphate of manganese; digitalis later on in full doses. When digitalis is followed by doubling of the beat or quickening of the rate of single beats I have been accustomed to replace it by tincture of cactus grandiflorus in doses worked up to 30 min. (or by cactina pellets—lately I have not used these); it carries the heart on until digitalis can be resumed in full doses without untoward effect. I have read that it is useless, but coloured water allows the heart to relapse while still liable to the unwished-for influence of digitalis.

R. W. M.

DISEASES OF THE ARTERIES AND ANEURYSM

The physiological function of the arteries is to convey to the various parts of the body the blood pumped into them by the heart. They are not mere mechanical tubes, but have elastic living walls whose healthy condition is of the greatest importance both for local and general circulation. The compelling pressure under which the blood flows is derived originally from the force of the heart-beat, and the intermittent pulsation in the arteries is converted into a regular flow in the capillaries by the elastic arterial walls and the resistance offered by the small arteries to the escape of blood through them. This resistance varies inversely as the calibre of the arterial tube, and therefore depends on the active muscular contraction or tone of the vessel walls. Arterial tone is itself dependent on the central nervous system through the vasomotor nerves and the vasomotor centres in the spinal medulla and medulla oblongata.

Therapeutically it may be advantageous to diminish or increase the quantity of blood flowing through a particular organ or part of the body, or to raise or lower the general blood pressure.

Alterations of Local Blood Flow.—The amount of blood arriving in a particular portion of the body can be decreased by making the afferent vessel smaller, provided no alteration is produced in the rest of the vascular area. This may be accomplished by direct compression, or by causing a reflex contraction of the vessel wall by means of cold applications. The supply of blood may also be diminished by making use of gravity, *e. g.* raising a limb above the level of the trunk decreases its supply owing to the difficulty of flow against gravity. So far no drugs are known which have a selective constricting action on particular vessels apart from a general effect on all the arteries.

The local supply of arterial blood may, on the other hand, be increased by placing a limb in a dependent position, or by causing a dilatation of the afferent vessel as by the application of warmth. A useful method of flushing a limb with arterial blood consists in first emptying it by the application of a Martin's rubber bandage: after the removal of this there is a temporary loss of arterial tone, with the result that a very large amount of blood flows into the limb, giving it a bright red colour. Massage,

besides pressing out the venous blood, leads to arterial dilatation, and so materially augments the flow through the part treated. Certain drugs have the reputation of bringing about local arterial dilatation; for instance, pilocarpine acts in this way on the arteries of the skin and the salivary glands. Digitalis is supposed to cause a special dilatation of the renal arteries, while constricting all the others: the exact mechanism by which digitalis works on the human system is still somewhat obscure, but diuresis is often produced apart from any effect on the heart.

The General Arterial Pressure, on the other hand, varies inversely as the size of the vessels, thus a general dilatation of the arteries brings about a fall of pressure, while constriction causes a rise provided the force with which the blood is pumped out of the heart remains the same. The arteries, and here the most important are the small ones, dilate under the influence of warmth (*e. g.* a hot bath), with exercise or massage, and with the administration of certain drugs. Exertion raises the pressure while it continues owing to increased vigour of the heart-beat and compression of the vessels by the muscular contraction, but this is followed by a fall that lasts longer than the original rise. Of course a fall of arterial pressure, provided it is not due to extreme feebleness of the contractions of the heart, leads to an increase of pressure in the capillaries and veins, and of the latter the large veins in the splanchnic area require special mention since they can contain the whole blood in the body. The arterial pressure can naturally be raised by pressing the blood out of these veins, as, for instance, by applying a tight bandage to the abdomen. On the other hand, a sudden diminution of external pressure here may lead to a dangerous fall of arterial tension, the patient bleeding, as it is said, into his abdominal veins.

When one comes to the treatment of an individual patient it has first to be considered whether his blood pressure is to be regarded as abnormally high or low. It is impossible to fix a standard of high or low pressure, and it must not be forgotten that the pressure gradually increases with age, so that what may be abnormally high in the young becomes quite normal in the middle-aged. Then, again, excitement, exertion or tobacco-smoking may cause a temporary rise of pressure, which as recorded by an instrument may mislead the observer. As a rule the physician has to deal with cases of abnormally high tension in persons over the age of forty, and in these a permanent maximum pressure of over 160 mm. of Hg. should be regarded with suspicion. It is important to recognise that sometimes the maximum pressure is decidedly raised without any increase in the minimum pressure, so that the mean is but little raised: these cases have not the same serious outlook as those where there is decided elevation of the mean pressure. Cases of high arterial pressure, especially where there is also disease of the arterial wall, are prone to paroxysmal attacks of further raising of the pressure which may last several hours. On the other side maximum pressures that do not reach 90 mm. of Hg. should be regarded as suspiciously low and as possibly in need of treatment.

Treatment of High Arterial Pressure.—Having decided that the pressure in a particular patient is abnormally high the physician has next to determine whether it is advisable to attempt to reduce it. In many persons a high pressure is compensatory and an efficient capillary circulation cannot be maintained without it. Here, obviously, it is inadvisable to spoil the proper working of the machine by trying to make one of its parts fit in with some arbitrary standard. Other persons feel all the better when the pressure is high, and unless there is urgent need for lowering it they should not be treated. The raised tension may occur in persons whose vessels are in themselves healthy, or in others where the arterial walls are already degenerate. There is a good deal of evidence that constant increased arterial pressure is one of the commonest causes of arterial degeneration, so that it is important to start treatment as early as possible, recognising that in no condition is the old adage that prevention is better than cure more apposite.

One finds that both arterial disease and increased arterial pressure are commonest in persons leading a sedentary life, whose labour is mental and whose recreations include a free indulgence in both eating and drinking, with elaborate cooking and a good deal of alcohol. There is, therefore, justification for the view that these are potent causes of the pathological abnormality, and the first essential of treatment is to remove the causes of disease. In the vast majority of cases, all that is necessary or advisable is to see that the patient does not work his bodily mechanism at too high a pressure. He should be relieved of some of the cares and excitement of business, his diet should be less ample, and the cooking less elaborate, and he should get regular moderate exercise in the open air in the form of riding, walking or golf. The consumption of alcohol should also be restricted and carefully regulated. In prescribing such a régime, it is important to avoid regarding the patient as in any way an invalid, since high arterial pressure is tending to become one of the favourite hypochondriacal fads of later middle age, but some such measures are required in all cases of decided high arterial tension.

Where the raised pressure is persistent, or where there are already signs of arterial de-

generation, further treatment may be necessary. The intake of salt and extractives should first be lessened. Thus soups must be forbidden, and meat should usually be boiled, as in this way the extractives are removed. Next, a still greater restriction of diet, especially with regard to the proteins, should be ordered, and an attempt made to lower the pressure further by the use of drugs, particularly those that cause a dilatation of the peripheral arteries. Unfortunately in these cases, an artificial reduction of tension is usually followed on cessation of treatment by a return to the original high level, while many patients are prone to paroxysms of high pressure lasting several days, and the passing away of such a paroxysm may unduly flatter the therapeutic measures.

The drugs with the most decided influence on the reduction of pressure are the nitrites. Some of these, such as amyl nitrite and nitroglycerine, have a rapid and considerable effect, which, however, only lasts a very short time, whereas the nitrites of sodium and erythrol act more slowly and less energetically, but produce a more prolonged result. The former are, therefore, more suitable where a rapid temporary decrease of pressure is desirable, *e. g.* in angina pectoris, and the latter are more adapted for continued administration where a more permanent effect is hoped for. Of other drugs, the benzoates and hippurates (*e. g.* 1–2 gr. of ammonium hippurate two or three times a day) are strongly recommended by Oliver, and these may be combined with nitrites. Oliver also advocates the combination of alkalies, with vaso-dilator drugs. Iodine in the form of potassium iodide has long held a reputation in the treatment of this class of case. Although it is impossible to demonstrate any direct effect in the reduction of tension, there is no doubt that the patients, particularly where there is some arteriosclerosis, feel benefit from the course of the drug, of which 3–5 gr. should be given three times a day over several months.

In renal disease, or in patients in whom cerebral hæmorrhage is threatening, the physician may feel it incumbent to produce a rapid and material reduction of pressure. Here bleeding is of great service, and it is in this class of patient that we so often see a marked improvement in the general condition after a smart epistaxis. Sweating, by means either of the hot-air bath or the hypodermic administration of pilocarpine, also assists in lowering the arterial tension and relieving the symptoms of the patient. In all cases of high arterial pressure it is important to see that the bowels are acting well and regularly, since it is possible that the original cause of the rise of pressure is some toxin of intestinal origin. Where the pressure is excessively high, a maximum of over 200 mm. of Hg., free purgation seems to assist in the reduction.

Treatment of abnormally low arterial pressure is but seldom required, except as an urgent condition due to shock, feeble cardiac contractions, etc. The necessity is adequately met by temporary measures which stimulate the contraction of the heart, cause a constriction of the peripheral arterioles or forcibly drive blood out of the abdominal veins. Thus the heart contraction may be stimulated by alcohol, ether, ammonia or strychnine, or even by direct irritation; the arterioles may be caused to contract by the administration of suprarenal or pituitary extract, which probably also stimulate the cardiac muscle: and the abdominal veins may be emptied by direct pressure, such as exerted by a firm bandage applied to the abdomen. It is remarkable that the blood pressure is not usually materially lowered in the condition to which the clinical term "heart failure" is applied, where there is general venous congestion and dropsy, except when the condition is extreme and death impending. Should the pressure be low any measure that results in improved action of the heart would tend to raise it to the normal level, so that free bleeding and the employment of such drugs as digitalis would incidentally improve the blood pressure.

Some persons enjoy good health even in spite of a constant pressure below the normal. Neither in these cases, nor where a low pressure is associated with chronic wasting diseases such as tuberculosis, is any direct treatment required. One special condition, Addison's disease, is accompanied by a considerable lowering of the arterial pressure, presumably because of the absence of the internal secretion of the suprarenal glands, and considerable benefit has been stated to have followed in some cases the supply of suprarenal extract from without, but, beyond this, measures directed towards the raising of the blood pressure do not seem to have been advantageous.

Treatment of Diseased Arteries.—Arterial diseases may be divided into those that are inflammatory and those that are due to degeneration. The arteries may be involved in adjacent acute inflammatory processes, but here no special treatment of the vessels is required beyond the measures taken to combat the local inflammation. Inflammatory lesions of the arteries are also common in many acute infections, such as rheumatism, enteric fever and smallpox, but they are always undiagnosed and are not adapted for special treatment. They are important, as they are aften the starting-point of degenerative processes and may lead to local weakness of the vascular wall. Of all the inflammatory processes, those due to syphilis are the most important. These affect both

the inner and middle coats and lead to thickening of the vessels and obstruction to the flow of blood. They are also frequently followed by degeneration. An energetic treatment with iodides (5–20 gr. of potassium iodide three times a day), to which some mercury (½ dr. of Liq. Hydrarg. Perchlor.) may be added with advantage, will often result not only in an amelioration of the symptoms, but also in an actual lessening of the morbid changes in the arterial walls.

The degenerative processes in arteries are frequently in their origin inflammatory, and are generally accompanied by the development of a great deal of fibrous tissue, which is commonly regarded as a chronic inflammatory change. It is hopeless to expect any return to the normal in vessels in which there is excess of fibrous tissue or atheromatous changes, though fibrolysin, which has considerable influence on scar tissue, has been suggested as likely to reduce the fibrous element in arteriosclerosis. Any definite result from the employment of this drug yet remains to be proved, and it is a doubtful question whether any reduction of the fibrous tissue is to be desired, as it has usually arisen in replacement of degenerated muscle or elastic fibres, and so helps to strengthen a weakened wall. The main aim and object of the treatment of degenerated arteries must therefore be firstly, if possible, to prevent the spread of the morbid process, and secondly to relieve unpleasant symptoms. The degenerate changes are often, but by no means invariably, associated with increased arterial tension, and experimental and clinical experience seems to point to raised blood pressure as a potent factor in their production. Hence, to prevent further spread of this vascular degeneration, attempts should be made if the pressure is high to lower it, but unfortunately it is just in these cases where the arteries are already diseased that it is most difficult to produce any permanent alteration in the blood pressure. Still, considerable benefit may be derived from increased open-air exercise, a reduction in the time spent on business, and some release from its cares, and a careful regulation of diet, especially in the limitation of proteins. These patients are also usually decidedly the better for a course of iodides (Pot. Iod. 3 gr. three times a day), which may be continued over several months, and care should be taken that the bowels act regularly. The symptoms accompanying arterial disease are mainly caused by the resultant deficiency in the blood supply to certain organs of the body, which is accentuated by the liability of diseased arteries to spasm. For instance, there may be sleeplessness, mental impairment and temporary paresis from cerebral anæmia, dyspnœa from interference with the coronary circulation, coldness of the extremities, and sometimes gangrene when the arteries of the lower limbs are affected. Local treatment can do but little in these conditions, and the best results must be expected from efforts to fit the work to the capacity of the damaged machine. The mental work of a man with sclerosis of his cerebral arteries should be limited, and the physical exercise of one with coronary disease should be regulated by what can be done in comfort and without breathlessness. By such means a partly worn-out machine may deliver without discomfort a decreased output of work over a good many years, when an attempt to maintain the original level would have led to an early breakdown.

Aneurysm.—The proper treatment of an aneurysmal dilatation of an artery depends both on its nature and on its position. The general aim of treatment is to cause an obliteration of the sac by inducing the blood to coagulate in it, but while this principle is applicable to saccular expansions from the side of the vessel it is obviously unfitted for fusiform dilatations of any artery that cannot with safety be completely closed. Since aneurysms arise owing to some imperfection of the arterial wall which tends to act towards the blood as a foreign body, coagulation can generally be induced by causing the blood to stagnate for a sufficient time in the aneurysmal cavity. In the peripheral parts of the body this can be brought about by surgical means, *e. g.* the blood flow into the tumour may be prevented by compressing or tying the vessel between the sac and the heart, or where such operations are not suitable the supply of blood may be greatly decreased by ligature of the artery beyond the sac, which stops the through flow of blood. Such surgical measures are, however, impracticable for the great vessels of the trunk, the thoracic and abdominal aorta, where a sudden cessation of the blood flow is incompatible with the continuance of life. It is true that cases of complete obstruction of the descending thoracic aorta are known, but they are usually of congenital origin or, if they arise after birth, are of very slow development, so that ample opportunity is allowed for the establishment of a collateral circulation. The abdominal aorta may, it is true, be temporarily compressed by means of a suitable apparatus, but as a rule aneurysms of the great thoracic and abdominal arteries will require treatment fashioned on other lines to that suitable for the limbs. Still, surgical measures to promote coagulation have been devised and practised. For instance, foreign bodies (a considerable length of silver wire) have been introduced into the aneurysmal sac, and the inner surface of the sac has been scarified by the surgeon so as to cause it to act towards

the contained blood like a foreign body. Again, dilatations of such vessels as the innominate, left carotid or subclavian, may be treated by distal ligature, and aneurysms of the iliacs by temporary compression of the abdominal aorta. Then, again, coagulation in trunk aneurysms has been brought about by passing an electric current through the blood, two fine electrodes being introduced into the sac and a constant current passed through. Nevertheless, it is evident that the cases suitable for surgical interference are limited in number and that the treatment is fraught with special dangers.

Medical treatment may be divided into attempts to cure the aneurysm, to arrest its further growth or merely to relieve the unpleasant symptoms.

Treatment intended to cure the Aneurysm.—The fact that salts of calcium increase the coagulability of the blood has naturally led to their being recommended in the treatment of aneurysm; 10 gr. of the lactate may be given three or four times a day. Gelatine also increases the coagulability of the blood and was proposed by Lancereaux as a subcutaneous injection with the idea of assisting the coagulation in the aneurysmal sac. Lancereaux injected 3 oz. of a 2 per cent. solution of gelatine in 0·7 per cent. salt solution every third day into the flank or buttock for thirty or forty injections, and reported some very favourable results. Subsequent observers have failed to confirm this favourable opinion, perhaps because gelatine, as experiments have shown, quickens the blood flow. On the other hand, a decreased supply of blood to the sac might be supposed to favour the occurrence of coagulation there, applying the same principle as the surgical treatment of aneurysm in the limbs, and such a decreased supply would result from a general diminution in the blood flow. A decrease in the general blood flow would ensue in abstention from all bodily exertion, as in absolute rest in bed over several months, provided that active measures be taken to reduce the arterial blood pressure. This line of treatment was suggested long ago by Morgagni, who advocated in addition to absolute rest the abstraction of small quantities of blood, 6 to 10 oz., at intervals of a week. In more modern times it has been supported by Tufnell of Dublin, who in order to get sufficient reduction of the arterial pressure also advised that the intake of nutriment, both solid and liquid, should be reduced to the minimum necessary to support life. Tufnell's method has been widely practised, and it has been found possible to reduce the intake gradually to the following amounts and even to continue this very meagre diet for several months.

Breakfast.—2 oz. of bread and butter; 2 oz. of milk or tea.

Dinner.—3 oz. of mutton; 3 oz. of potatoes or bread; 4 oz. of claret.

Supper.—2 oz. of bread and butter; 2 oz. of tea.

That is to say, 10 oz. of solid food and 8 oz. of fluid in the twenty-four hours. Sometimes the absolute rest and restricted diet have been employed alone, sometimes conjoined with periodic blood-letting and, of course, the treatment may be combined with the administration of calcium lactate, potassium iodide or other drug. Good results have been recorded as the result of this régime apart from the mere amelioration of symptoms. Still, coagulation in the sac is by no means certain to follow; for instance, in a case seen by the writer as a student, which had been treated in this way for about eighteen months, the aneurysm, which from clinical evidence was supposed to be closed by laminated clot, ruptured about two years later, and at the post-mortem examination there was no evidence of any clot at all. There is naturally considerable difficulty in persuading patients to undergo such a very unpleasant régime, and the medical attendant has to consider whether he is justified in urging its adoption in the absence of any certainty as to a cure resulting.

Treatment designed to prevent further Extension of the Aneurysm.—Where the aim in treatment is not to bring about a cure, but merely to prevent the further growth in the size of the tumour and to guard against the giving way of its walls, the proceedings have to be somewhat similar to those that have been recommended with a cure as their object.

Aneurysm is caused by the giving way of a weakened spot in the arterial wall, or a general dilatation of the whole vessel, owing to the pressure transmitted by the blood. The weakening of the wall is due either to poisons or to degenerative processes following increased arterial tension; there may also be a sudden internal injury of the vessel wall from the strain of violent muscular effort. Naturally, the increase in size of an aneurysmal tumour depends directly on the pressure tending to expand it and inversely on the resistance to expansion offered by the wall of the sac and the surrounding structures. This resistance can be very little influenced by treatment, except by inducing coagulation to thicken the sac wall. Thus treatment has to be directed to diminishing the expanding force from within and to preventing, if possible, the extension of the morbid changes in arterial walls. Care has, therefore, to be taken to eliminate those conditions of diet and exertion which tend to raise arterial pressure and to cause vascular degeneration as well as to prevent toxæmia. As a very large proportion of cases of aneurysm arise from syphilitic disease of the vessels, the counteraction of any syphilitic taint is naturally

of the first importance. One can hardly expect treatment with antisyphilitic remedies to influence favourably a vessel wall that has already given way, yet there is a large amount of clinical evidence that the administration of iodide of potassium has a beneficial effect on the patient and his symptoms, especially when there is a past history of venereal disease. Thorough treatment may also be expected to prevent further vascular disease. It is, therefore, advisable to combine a course of iodides with measures calculated to reduce the blood tension. A course of treatment such as has been advocated for the cure of aneurysm of the thorax or abdomen frequently results in great relief of symptoms, and the disabilities do not return for a considerable time after the patient has returned to more or less ordinary life. One is justified in these circumstances in hoping that the vascular tumour, if no smaller, has at any rate not grown larger. To attain this end the régime does not require to be anything like so rigorous as has been proposed with the idea of producing a cure; for instance, the confinement in bed may be limited to six to twelve weeks, and the reduction of solid and liquid intake need not be such as to cause the patient discomfort. Coagulation may occur in the sac, though it is rather less probable than with the stricter régime. When the patient is again allowed to move about he must be warned of the danger of any sudden or violent exertion.

Symptomatic Treatment.—The symptoms of which the patient complains and for which he demands relief are mainly due either to stretching of the arterial walls or to pressure of the tumour on adjacent structures. They may be completely absent, but usually cause a good deal of discomfort. Pain may be caused by stretching of the walls of the aorta, and seems to be most severe and characteristic in disease of the ascending part of the arch, when it usually spreads over the right side of the chest and down the right arm to the fingers. But severe pain may also result from compression and erosion of bones, either vertebræ or ribs, and then is localised and aching in character. Pressure on nerves besides causing pain may lead to spasm, *e. g.* of the adductors of the larynx, or to paralysis. Pressure on the œsophagus causes dysphagia and on the trachea or bronchi brings on stridor or dyspnœa and later hæmoptysis owing to leaking of the aneurysm before rupture, while compression of the veins results in congestion and swelling behind the obstructed point. All these symptoms may be considerably relieved by rest in bed, and the relief seems to be materially increased by the administration of potassium iodide in doses of 3 gr. three times a day even where there is no syphilitic taint. Further measures are, however, usually required. For instance, pain has to be treated by local applications such as belladonna plasters, ice-bags or poultices, and in many cases these have to be supplemented by the hypodermic injection of morphia. Still, after a few weeks in bed and the above remedial measures many patients are able to get about again for a considerable period in fair comfort. Dyspnœa, which is often a troublesome symptom, whether it arises from pressure on the air tubes or from concurrent bronchitis, may also be usually much relieved by rest and the ingestion of potassium iodide. If the bronchitis is severe it may require treatment with expectorants such as ammonia, or, if there is much secretion, with belladonna. Sometimes the dyspnœa becomes urgent and is then best relieved by venesection. Hæmoptysis is often a sign of impending rupture into the trachea or a bronchus and necessitates absolute rest.

Spasm of the laryngeal adductors gives rise, of course, to urgent danger and may require tracheotomy to ward off death, but in less serious cases an attempt may be made to overcome the spasm by the inhalation of chloroform. Cough may be very distressing and is best treated by some form of linctus containing morphia. Nothing can be done directly for the relief of pressure on the œsophagus, with its attendant difficulty in swallowing, but this discomfort is often ameliorated with the other symptoms by rest in bed. The possibility of aneurysm as a cause of dysphagia must be remembered, as the passage of an œsophageal bougie may lead to fatal rupture. Now that the progress of food down the gullet can be seen by means of bismuth and the X-rays no bougie should be passed until the absence of a thoracic shadow with the X-rays has negatived the diagnosis of aneurysm of the descending aorta.

THROMBOSIS AND EMBOLISM

The Treatment of Thrombosis.—Thrombosis of any part of the vascular system is rarely, if ever, primary, so that it behoves the physician to bear in mind the possibility of its recurrence, and to take steps to prevent it whenever attending a patient suffering from any of the diseases with which it may be associated. There are many factors at work to produce thrombosis, and to treat the condition rationally it will not be out of place to mention them. They are—(*a*) Injury to the vessel wall, caused either by the local action of microbes or their toxins, or else by mechanical means. (*b*) Slowing of the blood stream, due either to some local obstruction or to general enfeeblement of the circulatory organs. (*c*) Altered composition of the blood.

The Prevention of Thrombosis.—The following general indications for the prevention of thrombosis arise from the consideration of the etiological factors.

(a) *To Eliminate and Neutralise Toxins.*—This is desirable from every point of view and especially to prevent thrombosis in infections in which it is likely to occur, such as puerperal sepsis and pyogenic infections generally. If of streptococcal origin, polyvalent antistreptococcal serum should be administered, and in the less acute cases an autogenous vaccine prepared. Whenever possible other infections should be treated on similar lines.

The patient should be encouraged to drink fluids freely, and in severe cases rectal salines, or better, continuous subcutaneous infusion of normal saline solution employed. Auto-intoxications such as gout should be treated in the appropriate way to eliminate the toxin.

(b) *To Maintain the Circulation at a Good Level.*—This is most likely to be required during the convalescence from a prolonged fever such as typhoid, and in cachectic conditions. General tonics should be prescribed—nux vomica or strychnine with a dilute mineral acid and bitter infusion—and as much nourishing food given as possible. Alcohol is indicated if there be much exhaustion, and a reliable preparation of digitalis if there be signs of marked cardiac failure.

Special care should be taken during the night when the circulation is at its lowest ebb. The patient should be kept warm, and encouraged not to lie with his legs crossed, as it is probable that the pressure exerted by the one knee on the superimposed femoral vein may be sufficient to obstruct the blood flow in it, and even to injure the endothelium, whereby thrombosis may be produced. It is a useful practice to have the legs of those who are confined to bed for any length of time gently rubbed three or four times a day. The venous circulation is considerably aided by this means.

(c) *To Maintain a Chemical Condition of the Blood Unfavourable to Thrombosis.*—The attempt may be made to diminish the amount of calcium salts in the blood. Sir A. E. Wright and Lieutenant Knapp have pointed out that a patient suffering from typhoid is kept almost entirely on a milk diet—milk containing a large amount of lime salts—and they advise the addition of sodium citrate to the milk (30 gr. to the pint) as soon as the danger of intestinal hæmorrhage has been surmounted. This alters the ionisation of the calcium, making it unavailable for blood coagulation, and at the same time the casein is made more easily digestible. All meat jellies contain a large amount of calcium salts, and are therefore better avoided. Citric acid (20 gr. every four hours for three or four days) or dilute phosphoric acid ($\frac{1}{2}$ dr. three times a day) may also be administered. The patient should drink plenty of natural lemonade or lime-juice. Addis questions the correctness of Wright's view; his experiments go to prove that the coagulation time of the blood is unaffected by citric acid given by the mouth.

Ammonia is believed to hinder blood clotting; Liq. Ammoniæ (20 min.) or Sp. Ammoniæ Aromat. (1 dr.) may be given frequently well diluted.

In conditions associated with cyanosis oxygen inhalations may be of service, for blood containing a large amount of CO_2 and deficient in oxygen clots readily. The application of six or seven leeches may be efficacious to prevent venous thrombosis; the beneficial effects of leeching may rather be due to the hirudin injected (which is a powerful anti-coagulant) than to the amount of blood abstracted.

The General Treatment of Thrombosis.—All that has been written under prophylactic treatment is equally applicable when thrombosis has occurred. The main indication in treatment now is to assist in the establishment of an adequate collateral circulation, so as to avoid the danger of gangrene from arterial thrombosis, and the effects of passive congestion from venous thrombosis. In cases of venous thrombosis it is of the utmost importance to guard against the danger of detachment of pieces of clot, which may give rise to fatal pulmonary embolism. This is best prevented by the maintenance of absolute rest, which is also an important factor in establishing the collateral circulation, so the necessity of it must be impressed on the patient.

Operative treatment is often necessary in cases of septic thrombosis, especially of the venous variety. In septic thrombo-phlebitis ligature of the vein is performed above and below the thrombosed area, and, if possible, the affected part excised. Gangrene, the result of arterial thrombosis, should be treated on ordinary surgical lines.

The Treatment of Special Forms of Thrombosis

Thrombosis of the Veins of the Lower Extremities.—This is the form of thrombosis most frequently met with. It occurs as a complication or sequel of infectious and general diseases, and also as the result of local causes such as an attack of pulebitis associated with varicose veins.

The patient must be sent to bed at once; he should lie on his back with the affected limb supported on a well-padded back-splint, the lower end of which should be raised about six inches. If the thrombus extend as high as the pelvic brim, the hip-joint should be fixed by putting the patient on a Thomas' hip-splint. A wire cage should be placed over the limb to remove the pressure of the bed-

clothes. The whole limb should be wrapped in cotton wadding or gamgee-tissue, and if there be much pain, a boracic fomentation, or hot lead and opium lotion (Liq. Plumbi Subacetat. 2 dr., Ext. Opii Liq. 4 dr., Aquam ad. 1 pint) applied on lint over the vein. In some cases more relief may be obtained by the application of dry heat, or of an ice-bag. The wadding and fomentations should be kept in position by a many-tailed flannel bandage.

If pain be not relieved by these local applications, aspirin (10 gr.) phenacetin (10 gr.), or in severe cases opium may be given internally. The patient should be cautioned against any sudden movement, and such acts as straining at stool and coughing prevented. The length of time the patient should stay in bed will depend largely on the severity of the attack. In a case of moderate severity, it is generally safe for him to get up at the end of six weeks, for by this time organisation of the thrombus will be well advanced. Active treatment should not be commenced until the temperature has been normal and all local tenderness has disappeared for three weeks. At first, slight, passive movements of the limb are executed; these are gradually increased, and after three or four days gentle massage is begun, avoiding the course of the vessel. After these manipulations have been performed for a week, the patient is permitted to move the limb himself, and a week before getting up the splint is removed. Before he gets out of bed, it is well to bandage the limb lightly from the foot upwards. He should be cautioned against standing for any length of time, and advised to rest with the leg raised; constipation must be avoided and no tight clothing allowed to constrict the limb. If, in spite of these precautions, œdema occur, it is best treated by careful massage, electricity and bandaging. A Crepon Velpeau bandage is much the best; it is elastic, soft, warm and porous. When a bandage of this material is used, it is rarely necessary to have resort to an elastic bandage or stocking.

Thrombosis of the Veins of the Upper Extremities.—This is treated in the same way as the similar condition of the lower limbs, except that the arm need not be put on a splint, but supported on a pillow at a slightly higher level than the body. Three weeks after all active manifestations have subsided the patient may be allowed up, the arm being kept in a sling for another two or three weeks.

Cerebral Sinus Thrombosis.—The non-suppurative form occurs occasionally in chlorosis and other states of exhaustion. The treatment is principally that of the anæmia together with the general measures mentioned earlier in this article. The patient should be kept in bed with the head almost flat, and not allowed to lie with the neck bent for fear of causing obstruction to the venous return which would favour an extension of the thrombosis. The suppurative form occurs most frequently in the transverse sinus as a complication of middle-ear disease. The treatment is largely surgical: the jugular vein is tied, the transverse sinus exposed, and the infected clot removed.

Portal Vein Thrombosis.—The non-suppurative form is usually associated with marked and rapidly recurring ascites, and with other signs of portal obstruction. Beyond paracentesis, the treatment is that of the causal condition (*e. g.* advanced hepatic cirrhosis); in some cases the Talma-Morrison operation may relieve the patient.

Suppurative pylephlebitis is generally fatal; the treatment is that of the primary disease. (See *Diseases of Liver.*)

The treatment of other forms of venous thrombosis is not given in detail, as it consists in carrying out the general principles described above.

Arterial Thrombosis

Thrombosis of the Cerebral Arteries. (See *Vascular Diseases of the Brain.*)

Thrombosis of the Arteries of the Extremities.—Arterio-sclerotic changes associated with old age and serious constitutional diseases may give rise to thrombosis of the arteries of the extremities. The arteries of the lower extremity are most frequently affected. A good deal can be done to prevent senile gangrene. The feet should be warmly clad in thick woollen socks, and old people should be careful to guard against any abrasion of the skin, which may allow the entrance of organisms. The same precautions ought to be taken by diabetics, as they, too, are specially liable to arterial thrombosis and gangrene. The treatment of the actual condition is the same as that of embolism of the corresponding arteries, to the description of which the reader is referred.

The Treatment of Embolism.—There are several varieties of embolism. In the ordinary use of the term, the embolus is understood to be a piece of detached thrombus, or vegetation from a cardiac valve. Fat embolism, air embolism, and embolism due to tumour cells, parenchyma cells, parasites, bacteria and foreign substances also occasionally occur.

Every precaution should be taken to prevent embolism. The general indications in treatment are the same as those already considered for thrombosis.

Pulmonary Embolism.—One of the branches of the pulmonary artery becomes blocked by a mass of clot dislodged from a vein. This is most frequently seen after operations (especially on the pelvic organs) and as a complication

of the puerperium. Everything possible should be done to prevent this disaster. After any major abdominal operation the patient should be kept quiet in bed for three weeks and cautioned against any severe effort or sudden movement. This is all the more important if the condition be an infective one. As much fluid should be introduced into the system as possible, and the other treatment described under the prevention of thrombosis carried out. In the cases in which pulmonary embolism has occurred, the patient usually appears to be making an uneventful recovery until one day—frequently about a week or ten days after the operation—extreme dyspnœa and cyanosis, suddenly appear, and death ensues in a few minutes.

The patient should be propped up in bed; oxygen should be inhaled, and also whiffs of ammonia vapour. Diffusible stimulants such as ether and brandy should be given subcutaneously, and atropine sulphate ($\frac{1}{100}$ gr.), strychnine sulphate ($\frac{1}{30}$ gr.), and adrenalin (10 min. of the 1 in 1000 solution) administered hypodermically. Hot fomentations should be applied over the heart. Trendelenburg and others have performed pulmonary arteriotomy, but so far the operation has not been successful. In slight cases, which are more frequently the result of cardiac thrombosis associated with heart disease, the above treatment should be carried out, the side may be strapped for the relief of pain, and the hæmoptysis which is often present treated on the ordinary lines.

Cerebral Embolism.—This is another serious form generally occurring as a complication of either acute or chronic endocarditis. The treatment is that of the primary disease and of the resulting paralysis.

Embolism of the Splenic Artery.—Strapping the lower ribs may relieve the pain. In infective cases an abscess may form which should be treated surgically.

Embolism of a Renal Artery.—The patient should be put on a milk diet. The pain and hæmaturia may be lessened by poulticing the loins or by dry cupping.

Embolism of the Mesenteric Arteries.—If the collateral circulation be not rapidly established, gangrene of the intestine occurs. The only treatment likely to save the patient is the resection of the affected loop of bowel.

Embolism of the Arteries of the Upper and Lower Extremities.—The popliteal artery is the most frequently affected. In embolism of an artery of the upper limb occurring in a young subject, an adequate collateral circulation may be established, but frequently gangrene results. As soon as possible the limb should be painted over with a solution of iodine (3 per cent.) in rectified spirit or acetone, and then enveloped in sterilised cotton wadding or gamgee-tissue, so that if gangrene occur, there may be no infection from the outside. The limb should be slightly elevated on an inclined plane and kept warm. Opium may be required for the relief of pain. If gangrene ensue, it is for the surgeon to decide the time and site of amputation. Arteriotomy with the removal of the embolus has been attempted in the more accessible arteries, and with the improved surgical technique introduced by Carrel may become the recognised method of treatment in the future.

Fat Embolism.—Fat embolism is sometimes seen as a complication of fractures and other injuries. It is less likely to occur, if the blood-vessels and fat in the affected area be injured as slightly as possible by the manipulations of the surgeon. The lungs being the principal organs affected, the treatment is that described under pulmonary embolism.

Air Embolism.—If a large vein be injured in the course of an operation, and air gain entrance into it, air embolism is produced. This most frequently occurs during operations on the neck. The surgeon should immediately apply digital pressure over the wound in the vein, and if urgent symptoms appear, an attempt may be made to force the air onwards by injecting normal saline solution into the vein, or it may be possible to force air out of the opening in the vessel by rhythmical compression of the thorax.

Air embolism produced as the result of the activity of such organisms as the B. ærogenes capsulatus, requires as such no special mention; the treatment is that of the primary infection.

P. H.

TREATMENT OF DISEASES OF THE BLOOD AND BLOOD-FORMING GLANDS

DISEASES OF THE BLOOD

Pernicious Anæmia

Pernicious anæmia is a well-defined clinical entity associated with a typical blood picture, but it has not been proved that the disease is essentially specific and dependent upon a constant cause. The fact that certain known poisons, such as that of the parasite bothriocephalus latus, can produce an anæmia almost exactly resembling pernicious anæmia, suggests that a variety of unidentified poisons may be

responsible for the disease, and hence the first step in treatment of any case must be an attempt to discover possible sources of poisoning.

The clinical course of pernicious anæmia strongly supports the view that it is a chronic infective condition and Hunter believes that it is due to a "specific hæmolytic infection" contracted from drains and favoured by the presence of long-standing oral and gastric sepsis which is usually of streptococcal origin. The common occurrence of alimentary disturbances together with the results in some cases of antiseptic treatment, certainly suggests that these have some intimate or even causal relationship to the disease. But whatever view be taken of the nature of pernicious anæmia, it must be recognised that acute, subacute and chronic cases occur and that all save the most acute show spontaneous remissions and relapses. Only careful observation and prolonged experience can justify pronouncement upon the value of remedies which may be employed, therefore, and improvement must not be allowed to arrest treatment.

1. *Investigation of the Case.*—Exclusion of the recognised parasitic causes of anæmias of pernicious type is necessary, and it is to be remembered that pregnancy and carcinoma of the stomach are sometimes associated with a similar condition. Careful investigation of possible infective foci must be made, particular attention being paid to the state of the teeth, gums and tongue, and an attempt should be made to isolate any predominant organism present. In cases with intestinal symptoms a bacteriological examination of the stools may reveal the presence of streptococci in unusual numbers, and whenever an organism which appears to be acting pathogenically can be isolated, whether it be from the fæces, the mouth or elsewhere, it should be used in preparation of a vaccine.

2. *General Hygiene.*—Rest in bed should be enjoined until recovery is evident, and fresh air is always important. The diet must be adapted to the gastro-intestinal condition, and in acute cases or during the acute stages of the more chronic types of disease solids are not usually tolerated. Gulland urges restriction to milk and farinaceous foods in such circumstances and prohibits all meal preparations until the patient is definitely recovering. Experience of each individual case will ultimately determine the diet which is most suitable, and dyspeptic symptoms are to be treated by the ordinary methods. When digestion is good and the patient is in a chronic stage as liberal a diet as possible may be allowed.

3. *Drugs.*—Administration of arsenic is certainly one of the most valuable methods of treatment in this disease. Liquor Arsenicalis is the preparation most commonly given, and commencing with 3 min. three times a day after food, the dose is generally increased by addition of 1 min. about every three days until 15–20 min. are being taken thrice daily if possible; but Hunter thinks that smaller doses up to 5 min. are equally effective. Some patients do not take arsenic well and in all cases symptoms of poisoning (nausea and vomiting, neuritis, pigmentation, etc.) must be watched for and use of the drug suspended if necessary. Even with the most tolerant it is advisable to allow occasional intermissions if large doses are being given, and during the periods of relative recovery the dose may be reduced to 2 or 3 min. The organic compounds of arsenic (atoxyl, orsudan, soamin, etc.) have not proved convincingly successful, and although recovery after intravenous injection of salvarsan is reported, most observers have found the result to be but transient benefit or even hastening of the end.

Iron is useless.

Glycerin by the mouth in doses of 2 dr. three times a day is said to have brought about recovery. Bone-marrow has been given in many different forms but is of doubtful value; certainly most of the commercial preparations are useless, and marrow should be obtained from fresh bones and given raw if the method is to have a fair trial.

Inhalation of oxygen has not been found useful by most observers.

4. *Disinfectant and Specific Treatment.*—Systematic attention to the infective foci already mentioned is of the first importance in the treatment of pernicious anæmia. The teeth must be scaled and the gums thoroughly disinfected, dead and carious teeth must be removed, and if there be definite pyorrhœa alveolaris it may be necessary to extract even apparently sound teeth. Hunter advises salicylic acid or salicylate of bismuth as a gastric disinfectant, and mercurials, such as the perchloride or grey powder, for the intestines. β-naphthol (10 gr. t.d.s. in cachets) or izal oil (2 min. in capsules before and after each meal) are excellent, especially in cases with diarrhœa. Gentle purgation is sometimes followed by improvement, but excessive looseness of the bowels is to be avoided.

In addition to the use of chemical disinfectants, vaccination may be employed to increase the resistance of the patient to specific infections associated with the disease. These, as has been said, are usually streptococcal, and the principles of vaccine therapy are discussed elsewhere.

Simultaneously with this, or even in absence of definite evidence of streptococcal infection, polyvalent antistreptococcic serum may be injected subcutaneously in doses of 10 c.c. on alternate days for two or three

weeks. Some observers maintain that normal horse serum is as useful as a specific immune serum, but it cannot be said at present that either is of proved value.

Gastro-intestinal disinfection, vaccine and serum therapy, and administration of arsenic may be employed simultaneously, but a second course of serum therapy must only be undertaken with due regard to the dangers of anaphylactic shock, since anaphylaxis, a condition of hypersensitiveness to the foreign serum, is developed about nine to thirteen days after an injection if no intervening injection has been given. The danger may be modified by subcutaneous injection of a small dose of serum (*e. g.* 1·0 c.c.) six to twelve hours before the remainder is injected, and all injections of the second series should be made very slowly.

Transfusion of blood from a healthy person has been tried with varying degrees of success. On the whole the results obtained are not encouraging, but the method has not yet been given a very thorough trial, for the technique is difficult and too advanced cases have usually been selected. Probably small and frequently repeated transfusions are to be preferred to a single large transference of blood, and this would practically prohibit the employment of vascular anastomosis. But ample experience in the treatment of other diseases by transfusion has shown that a syringe method (which cannot be described here) may be safely used by a skilled operator, and transfusion deserves to be tried early if at all. It should not be regarded as a last resource.

The improvement which has followed splenectomy in some cases of pernicious anæmia, does not appear to be either more marked or more constant than that which is frequently seen during spontaneous remissions of the disease.

5. *Special Symptoms,* other than those gastro-intestinal disorders which have already been mentioned and including such conditions as muscular cramps, hæmorrhages, cerebral disturbances and cardiac failure should be treated upon their own merits as they arise.

Secondary Anæmia

There is no specific treatment for the secondary anæmias. Recovery is dependent upon removal of the cause, and when this has been achieved, fresh air and good food are of greater importance than iron or arsenic. Both these drugs may help, but their effect on the secondary anæmias is in no way comparable to that of iron in chlorosis, nor even to that of arsenic in some cases of pernicious anæmia. And it is to be remembered that both exert a tonic action in cases quite devoid of anæmia. Complete investigation of every case must therefore precede treatment, and when the primary disease causing the anæmia has been discovered attention to this and to the general hygiene of the patient will do almost as much as can be done.

Hæmorrhage is responsible for some of the severest and most acute of secondary anæmias, and not only for those resulting from such conditions as trauma, hæmatemesis, and menorrhagia, in which the bleeding is sufficiently obvious to attract immediate attention, but for others in which its occurrence is apt to be overlooked. A large single hæmorrhage from an unsuspected lesion such as a duodenal ulcer may produce no more suggestive symptoms than an attack of faintness followed by melæna and an acute anæmia. The patient very likely fails to notice the altered blood in the stools, and if a correct diagnosis be not made repeated hæmorrhage or even perforation may occur. Smaller but recurrent hæmorrhages, as from hæmorrhoids, may be neglected as trivial and yet produce a profound anæmia, and the strain which such more or less continuous bleeding throws upon the bone-marrow may eventually exhaust its hæmatogenous function with a fatal result. Various measures for dealing with hæmorrhagic and posthæmorrhagic conditions are mentioned below under the headings *Purpura* and *Hæmophilia.*

Secondary anæmia is a usual accompaniment of *other diseases of the blood,* such as leukæmia and purpuras of unknown etiology, and the treatment is that of the primary disease.

The importance of *septic infection* as an essential or contributing factor in the production of anæmia is frequently overlooked but has been much emphasised by Hunter. He points out the very common occurrence and insidious nature of oral, gastric and intestinal sepsis, and any of these conditions may be responsible for aggravating an anæmia which is primarily due to some independent disease. On the other hand they or other infective conditions such as chronic suppurative lesions of the nasal sinuses may by themselves produce a secondary anæmia of any degree.

In each case appropriate and energetic treatment must be adopted. The perfunctory use of a mouth-wash is almost valueless in cases of pyorrhœa alveolaris; many will require complete removal of the teeth; in others extraction of stumps and scaling will be necessary and the sockets of such teeth as remain must be kept thoroughly clean by swabbing with hydrogen peroxide (20 vols.), and then applying a 2 per cent. solution of iodine in spirit each morning and evening. The gastro-intestinal condition usually improves as soon as the mouth is disinfected, but alkaline mixtures will aid in reducing gastric catarrh, and intestinal antiseptics such as salol and β-naphthol (10 gr. of

each t.d.s., the latter in cachets) should be given if intestinal symptoms are present. Wherever the infective focus may be, disinfection can only be properly completed by the establishment of free drainage, but when this has been effected the resistance of the patient to the particular organism concerned may generally be raised by use of the appropriate vaccine. Autogenous vaccines are desirable, and therefore cultures should be made from the lesion as soon as it is discovered and before active local measures have been adopted. (See *Vaccine Therapy*.)

Anæmia may also be produced by the *acute specific fevers*, particularly by diphtheria and acute rheumatism, and by *chronic septicæmic conditions* such as malignant endocarditis.

Tuberculosis is another common cause of anæmia and is apt to escape notice; it should always be borne in mind, and definite attempt must be made to detect or exclude it in obscure cases. There may be no localising symptoms in the early stages of the disease, but a characteristic constitutional disturbance with slight evening pyrexia may rouse suspicions which are justified by the discovery of physical signs or a positive reaction to one of the tuberculin tests. And it is clear that exact diagnosis is the first step towards adequate treatment. For the methods of treatment to be adopted in the case of particular lesions, the article dealing with each must be consulted.

Syphilis may be as potent a cause of anæmia and as difficult of recognition as tuberculosis. It is sometimes overlooked because no history is forthcoming or because there are no obvious local lesions. A relative or absolute lymphocytosis in the blood may excite suspicion and a positive Wassermann reaction is conclusive if the patient has not acquired some other tropical protozoal infection; but on the other hand syphilis may be present without being wholly responsible for the anæmia, and the possibility of complicating or coincident lesions emphasises the necessity for a very thorough investigation of each case.

Malaria and the *intestinal animal parasites* will seldom escape detection if the possibility of their presence is considered, and examination of the blood and fæces may exclude them or indicate appropriate treatment.

Anæmia of almost any grade may be produced by inorganic poisons, such as *lead* and *mercury*, or by the more obscure toxins of *nephritis* and *malignant disease*. Occasionally a diagnosis of carcinoma, latent as regards localising phenomena, may be arrived at by a process of exclusion in a patient at or past middle age with a progressive anæmia of secondary type and gradual loss of weight and strength. But *inanition* from any cause also tends to produce anæmia.

Chlorosis

Iron is a specific remedy for this disease and usually suffices to effect a cure in spite of unfavourable general conditions, but it is important to regulate the mode of life of the patient and to treat special symptoms which may occur. There are four chief considerations.

1. *General Hygiene.*—Exercise must be limited so as not to aggravate the symptoms, for while it is true that fresh air is essential to complete recovery it is equally true that lassitude and dyspnœa, faintness and palpitation, indicate the need of rest. The idea that chlorotics should take walking or other exercise in the open air is not infrequently responsible for delay in recovery in spite of the administration of iron. In severe cases with much cardiac dilatation it is well to keep the patient in bed for two or three weeks until definite improvement is apparent, and the inclinations of the patient will seldom mislead in the regulation of physical exertion. But fresh air and as much sunlight as possible are desirable throughout the *whole* course of treatment, and every use must be made of the increased opportunities afforded by improvement in the general condition.

Diet should be generous, including meat, but it must be modified if necessary in accordance with the gastric symptoms which are so frequently present. All dyspeptic conditions may be treated by the usual methods, but they seldom contra-indicate the immediate use of iron and this alone often suffices to remove them. The most common disorder is hyperchlorhydria, a condition of increased secretion of hydrochloric acid into the stomach, and hence most cases in which symptoms are present are benefited by administration of alkalies before meals. Fats in the diet tend to inhibit acid secretion and are therefore well borne, whereas proteins such as meat foods excite secretion and should be given in small quantities only until they are well tolerated. Oatmeal, apples, spinach and the leguminous vegetables are rich in iron, but as this element can always be added in medicinal form its presence in articles of diet is not of the first importance in immediate treatment of the disease.

The use of alcohol is both unnecessary and inadvisable.

2. *Iron.*—The best form is the Pil. Ferri (B.P.), and this should be given in gradually increasing doses—one pill (5 gr.) three times a day after food for the first week, two pills three times a day for the second week, and then three pills three times a day for at least two months. The number may then be gradually diminished in mild cases, but treatment should never extend over less than three months, and in most cases a course of six months is

advisable. Failure is sometimes due to defective absorption of iron owing to the form in which it is given (old, hard, insoluble pills), but much more commonly to administration of insufficient quantities of the metal, and chlorosis shows a great tendency to relapse. The patient frequently considers herself cured in a few weeks owing to the marked improvement which occurs as soon as treatment is commenced, but steady persistence is necessary, and even when health is completely restored it is well to keep the patient under observation and to re-administer iron at once if any symptoms reappear.

Some patients do not easily take iron. The physician should not be too readily discouraged, but if Pil. Ferri persisted with causes dyspepsia, Ferri Carbonas Saccharatus or Ferrum Redactum may be tried. Either may be spread as a powder upon bread and butter or made up in cachets or lozenges commencing with doses of 10 gr. and 2 gr. respectively three times a day and gradually increasing to three times these amounts. "Bipalatinoids" of iron (Oppenheimer), which contain ferrous sulphate and sodium bicarbonate in separate compartments of the same gelatin capsule, yield a freshly precipitated and readily soluble ferrous carbonate when acted upon by the gastric juice and may be tried in intractable cases. The per-salts of iron are more irritating than the ferrous salt in Pil. Ferri, and the scale preparations are weak but well taken by those whose digestion is easily disturbed. Organic preparations are more easily taken by many patients, but they are undoubtedly inferior in hæmatinic value to the inorganic salts. All forms of iron should be administered after food. Arsenic is said to be useful in some resistant cases, but only in combination with iron. It may be given in the form of Liquor Arsenicalis or as Arsenious Acid mixed with iron in a pill, *e. g.*—

℞ Liq. Arsen. ♏ iii
Sod. Bicarb. gr. x
Tinct. Calumb. ♏ xx
Aq. Chlorof. ad ℥ i.

To be taken three times a day after food in addition to Pil. Ferri.

or

℞ Liq. Arsen. Hydrochlor. ♏ iii
Liq. Ferri Perchlor. ♏ xv
Spt. Chlorof. ♏ v
Inf. Quass. ad ℥ i.

To be taken three times a day after food.

or

℞ Ac. Arseniosi gr. $\frac{1}{30}$
Pil. Ferri. gr. x
Ft. pil.

To be taken three times a day after food, the arsenic being omitted and the iron continued or increased as the patient recovers.

3. *Regulation of the Bowels.*—Constipation is a usual but not invariable symptom of chlorosis. Its correction is of essential importance and in obstinate cases it is well to start with a dose of calomel and then to give salines for a few days to a week. But the best regular purge for routine purposes is aloes, and this may be given as Pil. Aloes et Ferri (B.P.), or in a pill containing Aloes 2–4 gr., with Ext. Nuc. Vom. $\frac{1}{4}$ gr. It is well to modify the dose so that it may be taken regularly *every* night and serve to keep the bowels freely open each day. A pill containing Ext. Cascaræ Sagradæ 2 gr., and Ext. Nuc. Vom. $\frac{1}{4}$ gr., is sometimes sufficient and preferable, but each case must be treated according to its response.

It is said that intestinal antiseptics (*e. g.* β-Naphthol, 10 gr. t.d.s.) combined with the use of iron improve the results of treatment, but their administration is seldom necessary.

4. *Special Symptoms*, such as headache, palpitation, dyspnœa and œdema of the legs are often markedly relieved by administration of digitalis—small doses (3–5 min.) of the tincture three times a day. But any of these symptoms, if at all severe, indicates complete rest in bed.

The amenorrhœa of which so many patients complain is not an urgent symptom and menstruation will be re-established as the general condition improves. Menorrhagia need never cause alarm and always ceases when the patient is kept at rest in bed with other treatment appropriate to chlorosis. Probably the actual loss of blood is not a serious matter, for the total volume of the blood is greatly increased in this disease, and some observers have reported beneficial results from repeated small bleedings by venesection during the course of treatment by administration of iron.

Phlebitis, which most commonly affects the veins in the lower extremities, must be treated by absolute rest with elevation of the affected part and application of hot fomentations or belladonna liniment to relieve pain if necessary. Gentle massage may be commenced after two weeks, and the patient may be allowed to get up at the end of three to six weeks according to the size of the vein affected and the extent of spread of thrombosis. Continued massage and firm bandaging will assist the establishment of an adequate collateral circulation if any œdema of the leg remains.

Neuralgias may be treated by the usual methods and generally clear up spontaneously as the anæmia disappears.

Leukæmia

The treatment of a disease which has, according to our experience, an inevitably fatal issue is apt to prove disappointing unless we recognise

those variations in its type which influence the immediate prognosis. In considering the treatment of leukæmia it is necessary to remember, therefore, that different cases of the disease vary greatly in acuteness or chronicity as well as in the nature of the tissues chiefly affected. As regards the latter, intermediate types appear to exist, but the two main groups—myelogenous and lymphatic—are fairly distinct, and as a rule the lymphatic cases run the more rapid course and are less amenable to treatment. Roughly it may be said that a case is unfavourable in proportion to the acuteness of its onset and course, the degree of anæmia and the preponderance, both relative and absolute, of lymphoid over myelocytic elements in the blood. Acute lymphatic leukæmia is seldom even checked, but chronic myelogenous leukæmia may present such remissions under treatment as to simulate complete recovery. In the former group of cases treatment is chiefly directed against symptoms, particularly hæmorrhage; in the latter a more definite attack can be made upon the pathological condition of the tissues which appear to be primarily affected.

1. *General Hygiene* should be regulated according to the suggestions made for cases of pernicious anæmia.

2. *Drugs.*—Arsenic often proves very valuable, producing marked though temporary improvement. The Liquor Arsenicalis is a convenient preparation and should be pushed to the limits of tolerance as in the treatment of pernicious anæmia (*q. v.*). In some cases the organic compounds such as atoxyl, soamin and orsudan, do good, and any of these preparations, preferably soamin, may be administered subcutaneously, 10 gr. doses dissolved in sterile distilled water being injected on alternate days until ten doses have been given. Owing to the tendency of this treatment to produce optic atrophy smaller doses (1–3 gr.) are now usually recommended, but hope and fear go hand in hand and some risk may be considered justifiable in treating so fatal a disease. Salvarsan and neosalvarsan have not hitherto proved of definite value.

Quinine in large doses has been advocated, and in a case under care of Dr. Drysdale, an acute myelogenous leukæmia with intestinal symptoms, naphthalene tetrachloride in doses of 7 gr. at first every three hours and later every two hours, produced such marked benefit as to constitute an apparent cure. But the patient relapsed and died from cerebral hæmorrhage a few months after leaving hospital.

The use of benzol, recently introduced by von Kiránye, has produced some brilliant results in cases both of myelogenous and lymphatic leukæmia. It would be premature at the present time to make a final pronouncement upon its value, especially as regards the permanence or duration of improvement, but benzol promises better results than have been obtained with any other drug. It is best administered in gelatin or keratin capsules each containing 0·5 gm. of chemically pure benzol and 0·5 gm. of olive oil. At first two capsules are given twice a day after the principal meals, and the dosage is then gradually increased until 3–5 gm. are being given daily. The larger doses may cause albuminuria or hæmaturia, and watch should be kept for other symptoms of benzol-poisoning such as giddiness, headache, abdominal pain, vomiting, purpura and anæmia. When the stomach is intolerant to benzol, smaller doses, up to 2 gm. in twenty-four hours, may be given subcutaneously mixed with an equal amount of olive oil, but this method is painful and has not been much used. The optimum dose must be determined by the tolerance and progress of each individual case and very frequent examinations of the blood are advisable. No patient should be treated with benzol unless close and continuous observation is possible. There is a tendency to some increase in the number of leucocytes in the blood at first, but after a little time (usually about two weeks) a fall begins and is accompanied by improvement in the general condition of the patient, diminution in the size of the spleen or glands, and increase in the number of red cells and amount of hæmoglobin in the blood. It is advisable to cease administration of the drug as soon as the leucocyte count falls to about 12000 cells per c.mm., as the diminution will tend to continue and might be pressed too far. One of the signs of benzol-poisoning is leucopænia. In cases of myelogenous leukæmia the differential leucocyte count gradually tends towards the normal, and in the most favourable cases myelocytes may disappear from the blood altogether, but in lymphatic leukæmia the proportion of mononuclear cells remains high, even when the total leucocyte count has reached normal limits.

Administration of benzol does not contra-indicate the simultaneous or successive employment of other methods of treatment, and these, particularly the use of X-rays, are always to be kept in mind.

3. *X-rays.*—Hitherto this has undoubtedly been the most generally effective method of treatment. It is suitable for all cases of myelogenous leukæmia, whether early or late, and for chronic cases of the lymphatic type. The rays are applied to the ends of the long bones, the sternum, spleen, liver and to any enlarged glands that may be present. One part may be exposed at each sitting and various methods are advocated, some workers advising short exposures (ten to fifteen minutes) every two or three days, others preferring

longer exposures at weekly intervals. The exact details of the technique employed should be determined by an experienced operator. But whatever practice be adopted it is important to avoid excessive applications, for after preliminary improvement this leads to progressive deterioration of the red blood cells, and ultimately, the leucocytes also being greatly diminished in number, the blood picture of pernicious anæmia may be reproduced. To guard against this it is therefore necessary to control the use of the rays by frequent hæmatological observations, attention being paid not only to disappearance of the excess of white cells, but also to the number and hæmoglobin-content of the red cells. Deterioration of the latter is an indication for immediate cessation of X-ray treatment.

The improvement in clinical condition, however marked, is probably only temporary, and after subsequent relapse X-ray treatment is usually less successful or even without effect. Occasionally X-rays appear to aggravate the symptoms and induce headache, lassitude and pyrexia; in such cases the use of the rays must be diminished or discontinued.

4. *Other Methods of Treatment*, mainly directed to the spleen, have so far proved to be useless, as might be expected when it is remembered that all the clinical and pathological evidence points to the involvement of the spleen as being a secondary phenomenon in the disease. Splenectomy is an unjustifiable and fatal operation in leukæmia.

Transfusion of blood from a healthy person has been tried by Crile and he cannot recommend it.

5. *Special Symptoms*, such as hæmorrhage, gastro-intestinal disturbances and cardiac failure should be treated by the usual methods.

Leukanæmia

This term has been applied to a group of cases in which the blood picture presents some of the features of leukæmia combined with others characteristic of pernicious anæmia. Most of such cases are probably examples of acute myelogenous leukæmia or of the last stages of the chronic form, and treatment should be carried out along the lines indicated above, although it is usually of little avail. Attention has already been drawn to the fact that excessive use of X-rays in cases of leukæmia may lead to a leukanæmic condition of the blood and benzol is likewise contra-indicated.

Chloroma

Practically no treatment is known for this condition, which is characterised by the presence of greenish, subperiosteal, lymphoid masses and the blood picture of lymphatic leukæmia. In the present state of our ignorance those methods which have been advocated for leukæmia should be applied and special attention should be directed to the more urgent symptoms such as hæmorrhage and pain. But the disease is invariably and usually rapidly fatal.

Purpura

Purpura is merely a symptom and rational treatment can only follow an accurate diagnosis of the condition to which it is due or with which it is essentially connected. Nevertheless, in a comparatively large number of cases purpura is the principal or even the only symptom, and no definite conclusion as to the etiology of these has yet been reached. There should be no satisfaction in labelling such cases "idiopathic" or "simplex," or in saying that they are manifestations of a latent rheumatism, for treatment remains purely empirical. But when some graver lesion underlying the purpura is discoverable this will be the first consideration in treatment, and no special therapeutic attention need be paid to the purpura itself except in so far as it may indicate a general hæmorrhagic tendency. The treatment here suggested, therefore, is not directed against subcutaneous hæmorrhage alone, but against spontaneous bleeding from any part of the body.

1. *General Hygiene.*—Complete rest in bed is advisable, at least until the purpura is definitely fading. The diet should be adapted to the general condition and the bowels should be kept freely open.

2. *Drugs.*—Arsenic is sometimes remarkably effective in cases of "purpura simplex," and small doses usually suffice, although it may be necessary to push the drug. Oil of turpentine also appears to have some value as a hæmostatic. It is usually given thrice daily in doses of 5–15 min. emulsified in mucilage of acacia (1 dr.). But Eustace Smith recommends that in the case of fairly robust individuals doses of 2–4 dr. may be given, mixed with an equal quantity of castor oil, one hour after food each morning. It is the non-purgative doses of intermediate size which are apt to cause nephritis. Calcium lactate 15 gr. three times a day for three days, sulphuric or aromatic sulphuric acid 15–20 min. three times a day, liq. adrenalin. hydrochlor. 5–30 min. every three or four hours, and liquid extract of ergot $\frac{1}{2}-1$ dr. three times a day, are all used, but without constantly convincing results. If there be good grounds for supposing the purpura to be a rheumatic manifestation it is rational to administer salicylates, but it is to be remembered that purpura is sometimes an indication of intolerance of this drug.

3. *Blood and Serum Therapy.*—Administration of human or animal serum by oral, subcutaneous or intravenous routes has proved effective in many cases of purpura and other spontaneous

hæmorrhages. Fresh human serum is preferable, but if this cannot be obtained animal serum, fresh drawn or already stocked, may be used. Normal horse serum, anti-diphtheritic serum and anti-streptococcic serum appear to be equally valuable, and doubtless owe their virtue to the same common constituent. Subcutaneous and intravenous injections are to be preferred to administration by the mouth or per rectum, but the danger of inducing anaphylactic symptoms by the use of animal sera must be remembered. The patient is immune to such phenomena if successive doses of serum are separated by intervals of not more than a week. If longer than this has elapsed, the intravenous method must not be employed and a small dose (*e.g.* 1·0 c.c.) should be given subcutaneously six to twelve hours before the remainder, the subsequent injection being made very slowly.

Within recent years improvements in technique have rendered practicable the direct transfusion of blood from a healthy individual into the circulation of a patient. Transfusion is to be preferred to serum therapy for several reasons. It is more effective in arresting hæmorrhage which is not under surgical control, and by replacing all the lost elements of the blood, it tends to relieve the hæmopoietic tissues when they are temporarily exhausted. Further, transfusion involves no wastage of the blood taken from the donor, and the risk of bacterial contamination during the process of transference is reduced to a minimum. In cases of extreme urgency the time which would be occupied in separating the serum is saved by the use of whole blood, but unless the loss of a few hours is likely of itself to prove fatal, the natural compatibility of the blood of the two persons concerned—patient and donor—should be determined by examination for isoagglutinins and isohæmolysins. These bodies are present in a small percentage of persons, and are probably a source of real danger in transfusion. Small amounts (10–20 c.c.) of blood or serum may be effective for hæmostatic purposes, but if the patient has bled freely, ½–1½ pints may be transfused from a healthy donor and the bulk of circulating fluid may be further increased, if necessary, by infusions of normal saline solution, or better, of Ringer's fluid.

When the patient is evidently suffering from loss of fluid, and so long as the source of the bleeding can be controlled, rectal, subcutaneous or intravenous injections of normal saline solution may be resorted to immediately and stimulants may be given freely. If, further, the tissues of the patient may be expected to make good the loss of specific elements of the blood, transfusion of large amounts will not be necessary, but where hæmorrhage may recur owing to imperfect control of the local lesion, the volume of the blood and the strength of the heart-beat are only to be increased by other means than transfusion of human blood when their diminution threatens to lead to a fatal termination.

4. *Local Treatment.*—In addition to the general treatment recommended above certain local measures for the control of hæmorrhage may be adopted. Direct pressure is one of the best, but it is not always applicable, either because the bleeding point is out of reach or because the blood oozes from a wide surface which presents no obvious lesion. Adrenalin (1 in 1000) is a useful local application, particularly to the mouth, gums or nose. In cases of hæmatemesis adrenalin may be given in 1 dr. doses by the mouth every hour for several hours. For hæmorrhage from the bowels Pil. Plumbi c̄ Opio is honoured by time, but the important constituent is probably the opium, and in any severe case of hæmorrhage, provided there be no acute cardiac failure, a hypodermic injection of morphine is valuable for stilling the patient.

5. *Joint Pains* are a frequent accompaniment of the idiopathic purpuras, and whether or not they be regarded as evidence of acute rheumatism, salicylates, particularly aspirin, may be employed in their treatment.

6. *Henoch's Purpura* is a sufficiently well-defined condition to deserve special mention, although its etiology is still obscure. The patient, usually a child, should be kept in bed, and nothing but iced milk should be given by the mouth. If the pain is very severe a hypodermic injection of morphine should be given, and small doses of opium (*e.g.* Tinct. Opii 3 min., or Pulv. Ipecac. Co. 2 gr., or Pulv. Cret. Arom. c̄ Opio 8 gr., for a child of twelve years) may be given regularly afterwards if necessary. Potassium iodide has been recommended, and a case is recorded in which adrenalin (1 in 1000) 2 min., and Liquor Arsenicalis 3 min., given every four hours, apparently dispelled the symptoms with remarkable rapidity.

In some cases at least there is evidence to suggest that a streptococcal infection may play a part in the disease, and a careful search should be made for infective foci, particularly in the tonsils. If such be found—and an attack of tonsillitis may have heralded the approach of characteristic symptoms—active disinfectant measures should be employed against it, and a vaccine prepared from the predominant organism may be administered as a prophylactic against further attacks. Tonsils which show signs of inflammation should be removed during a quiescent period.

Antistreptococcal serum has been advocated by some writers, but probably its value is not

dependent upon its specific nature and serum therapy may be employed on the lines laid down above.

The symptoms of Henoch's purpura frequently resemble those of intussusception very closely, and subcutaneous hæmorrhages may escape notice or only appear several days after the onset of pain. It may therefore be very difficult to distinguish between these conditions, and a further difficulty arises in that the two are sometimes associated, intussusception apparently being excited by the presence of submucous hæmorrhages in the intestine or by violent peristaltic movements. Rectal examination and palpation of the abdomen with the patient under a general anæsthetic may reveal the presence of an intussusception, but in the absence of definite physical signs in a doubtful case it is advisable to keep the patient under observation without immediately opening the abdomen.

Hæmophilia

1. *General Precautions.*—All persons known to be, or suspected of being, subjects of this disease should be most carefully protected from injury from their infancy onwards. The indirect violence of exertion may induce hæmorrhages into the joints and subcutaneous tissues and is therefore as much to be avoided as direct wounding of the skin. Extraction of teeth and other operative procedures are attended with grave risks and should only be undertaken in urgent circumstances and after due consideration. The fact that a boy of hæmophilic stock has never suffered from immoderate bleeding affords no guarantee of safety, for the hæmorrhagic tendency does not always manifest itself in the first few years of life.

Residence in a warm climate is advisable, especially during the winter, and hydrotherapy, particularly sea-bathing, seems to be useful as a prophylactic against spontaneous hæmorrhages. If sea-bathing is impracticable regular cold douches and cautious massage may be substituted. An ordinary diet may be taken and a liberal supply of milk should be included.

In regard to the question of marriage the law of transmission of hæmophilia must be remembered. The rule is that females of hæmophilic stock, while not themselves "bleeders," transmit the disease to the majority of their male descendants. A careful study by Bulloch and Fildes of all the reported cases shows that there is no sufficient evidence for the belief that females may occasionally be true bleeders, or that males, whether themselves affected or not, may transmit the disease; and so far as the consideration of marriage is concerned such doubtful possibilities may be neglected. Few hæmophilic males ever marry, however, and it is inadvisable that any should do so, but the risk which they incur is confined to the direct and indirect results of their personal injury. It is otherwise with the females of affected families, for they tend to be exceptionally fertile and may perpetuate the disease indefinitely through the female line to the males of any subsequent generations. It matters not that their brothers may be free from the taint, so long as their mother's brothers, or maternal grandmother's brothers, exhibited it. Marriage of all such women must be strongly condemned.

2. *Drugs.*—Calcium is the most vaunted drug for hæmophilia, and appears to be valuable in some cases, although much difference of opinion still exists with regard to the theory of its action. Doses of 15 gr. of the lactate should be given three times a day for not more than three days. Continued administration is said to diminish the coagulability of the blood, and hence treatment may be ordered for a day or two each week during the intervals of hæmorrhage. In the case of a patient who is actually bleeding a large initial dose (1 dr.) may be given immediately. But calcium is not readily absorbed, particularly, it appears, in some cases, and for these Wright commends a mixture of calcium lactate and magnesium carbonate in equal parts. Subcutaneous injections of calcium have been tried without special success, and the chloride causes local sloughing, while the lactate causes pain.

Wright recommends internal administration of extract of thymus, up to twenty 5 gr. tablets being given daily. Ovarian extract, thyreoid extract, adrenalin, turpentine, gelatin and perchloride of iron have all been given internally without definite benefit.

Inhalation of carbon dioxide (which may be generated in an ordinary Kipp's apparatus or supplied in cylinders) is said to check hæmorrhage and may be repeated as often as necessary. (Wright.)

3. *Serum Therapy* is the most valuable form of treatment at our disposal at present. Fresh serum, either human or animal, is the best, but if this cannot be obtained, the normal horse-serum now stocked, or even antidiphtheritic or antistreptococcic serum, when no other is at hand, may be used. Intravenous administration (10–20 c.c.) is the most effective method and the minute puncture necessary may be made where it can be easily controlled subsequently. Subcutaneous injection (20–30 c.c.) entails risk of hæmorrhage into the tissues, and ingestion by the mouth cannot be relied upon. It is stated that intravenous injection once per month suffices to prevent spontaneous hæmorrhages and even to render operative procedures safe, but the development of ana-

phylaxis must be borne in mind if animal sera are used, and injections at so long intervals are only safe when immunity to the particular serum employed has been maintained by repeated small injections at short intervals (less than a week).

Crile has found that direct transfusion from a healthy person gives good results, but the difficulties of the operation must be greatly increased when it is performed on a hæmophilic, and the syringe method should be employed in preference to a vascular anastomosis.

4. *Local Treatment.*—A large variety of local applications have been tried without constant success, *e. g.* 1 to 2 per cent. solution of calcium chloride, adrenalin (1 in 1000), 1 to 2 per cent. cocaine, gauze compresses soaked in 5 per cent. sterile gelatin and the actual cautery. Whenever possible local pressure should be employed, but the most efficient method of dealing with hæmorrhages from the skin or mucous membranes is the application of fresh blood (human or animal) or of extract of some highly cellular organ such as the thymus or testis, after removal of all blood-clot lying superficial to the bleeding point. Wright recommends the following method of preparation of this "physiological stryptic": Extract chopped thymus or testis (from calf or lamb) with ten parts of normal saline solution containing a trace of sodium bicarbonate. Add 1 per cent. carbolic acid and allow to stand for twelve to twenty-four hours if possible, but strain at once if necessary. To the strained fluid add 0·25 to 0·5 per cent. calcium chloride (weighed as crystals) and then apply directly to the bleeding surface on a plug of wool or lint with as much pressure as possible.

5. *Joint Affections* are treated by complete rest. Puncture of the joint is only indicated if the pressure of the effused blood becomes unbearable. After a few days, gentle massage should be applied to the proximal part of the limb, the joint being untouched and unmoved. Some degree of permanent deformity is practically unavoidable. A. E. S.

DISEASES OF THE SPLEEN

Splenic Anæmia

Although it is by no means proved that all the cases described under the title splenic anæmia are examples of one and the same disease, yet they form a fairly well-defined clinical group, and for purposes of treatment they may be considered together so far as our present knowledge goes. It need hardly be insisted that differential diagnosis from other diseases in which enlargement of the spleen, anæmia, hæmatemesis, etc., occur, must precede any rational therapeutic measures.

1. *General Hygiene.*—Fresh air is no less essential than in the treatment of other blood diseases, and rest and diet must be adapted to the symptoms of each case; there are no special indications. If the enlarged spleen causes much discomfort a belt may be used to support it.

2. *Drugs* do not appear to be of much value, but arsenic is generally used and is probably the best; it should be given in gradually increasing doses as in pernicious anæmia. Iron is useless and quinine and boracic acid have been advocated without much success.

3. *X-rays* applied to the spleen are certainly useful in some cases, causing a diminution in size of the organ with coincident improvement in the blood picture and clinical condition. But the results are palliative rather than curative, and excessive exposure to the rays may do more harm than good. It is therefore important to examine the blood at frequent intervals during this treatment and to regulate the applications accordingly.

4. *Splenectomy* has been followed by some remarkable successes and should be considered in every undoubted case of the disease. Whether recovery is really permanent remains to be seen, but it has been reported even in advanced cases with cirrhosis of the liver and ascites (Banti's disease). It must be remembered, however, that the operation is often attended with great difficulty and has an immediate mortality of about 12 per cent. in the best hands, the chief risk being due to hæmorrhage after separation of adhesions between the enlarged spleen and adjacent parts. The general condition of the patient must largely influence the result of surgical interference, and therefore the operation should be performed as early as is consistent with careful diagnosis. If the spleen is already much enlarged and fixed, a preliminary course of X-ray treatment may render its removal less difficult.

5. *Special Symptoms* must be treated as they arise. The most troublesome are hæmorrhages, particularly from the stomach, and here the blood comes from minute erosions of the veins without any ulceration recognisable by the naked eye. The usual principles governing treatment of hæmatemesis must be followed, but in view of the fact that there is no macroscopic ulceration, diet may be augmented more rapidly than usual and the Lenhartz method should always be adopted.

Acholuric Jaundice.—There are two types of this condition, congenital and acquired; and both present as their chief features splenomegaly, jaundice (which may be intermittent), anæmia and debility, while the red blood corpuscles show a pathognomonic increase of fragility. Splenectomy has produced uniformly good results in both types of case, and the absence of adhesions renders the operation relatively simple. It is not yet

possible to say whether the relief afforded by splenectomy constitutes a complete cure, but there is ground for hoping that it may do so; no other methods of treatment are of any value.

Von Jaksch's Anæmia

This condition, sometimes known as *Pseudoleukæmia Infantum* or *the Splenic Anæmia of Infancy,* is certainly quite distinct from the splenic anæmia of adults, although, like that disease, it is probably not to be regarded as a definite pathological entity. Attention must be paid to the general hygiene and the diet should be such as is indicated in rickets, including eggs, raw meat-juice and a liberal supply of milk. Iron and cod-liver oil should be given. Syrup. Ferri. Phosph. Co. is very palatable and efficient, and cod-liver oil is well taken when mixed with extract of malt in the proportion of one to four. Application of X-rays to the spleen has been advocated, but this is purely empirical and of doubtful value. Splenectomy should never be performed.

Erythræmia (*Splenomegalic Polycythæmia*)

Nothing is known concerning the etiology of this disease and at present treatment is very unsatisfactory. Bleeding gives marked but very temporary relief, and application of X-rays to the spleen, though usually of more permanent value, is not successful in all cases. In view of the suggestion that erythræmia is due to a hyperactivity of the erythroblastic elements of the bone-marrow analogous to the excessive leucoblastic activity in leukæmia, the effect of X-rays applied to the long bones is worth trying. A case has been reported in which treatment with benzol produced temporary benefit, the red blood cells falling from 9,000,000 to 6,700,000 per c.mm. This drug certainly deserves a trial, and should be employed according to the suggestions made for leukæmia. Splenectomy is never justified.

Other Diseases of the Spleen

The functions of the spleen are such that its removal from an otherwise healthy individual causes little or no disturbance of health. It is not surprising, therefore, that disease of the organ is usually manifested only by enlargement, and as primary splenic diseases are rare, attention is more often directed to the spleen for purposes of diagnosis than for treatment.

But while the primary condition is being treated, splenic symptoms may call for immediate relief. Acute stretching of the capsule may be diminished by free purgation, and pain due to perisplenitis by local application of hot poultices or of antiphlogistine. A chronically enlarged spleen may be supported by means of a suitable belt and pad; sometimes its size may be reduced by application of X-rays, and in some cases, even when the spleen is only secondarily involved, as in syphilis and malaria, improvement follows its removal.

The conditions dealt with below are those in which the spleen is wholly or mainly responsible for the symptoms of the patient.

Movable Spleen.—This is seldom found without some other morbid condition and is most commonly a part of a general visceroptosis. For purposes of treatment both the condition of the spleen itself and the symptoms which it is causing must be considered. If the organ be healthy save for its abnormal mobility it may generally be disregarded. It is doubtful whether belts applied to the abdomen will keep a spleen of normal size in its proper place. If the pedicle of the spleen becomes strangulated, immediate operation is indicated and the organ should be removed, but apart from this emergency surgical intervention may be justified by continuous pain, discomfort and anxiety, splenopexy or splenectomy being performed.

Rupture of the Spleen is a dangerous and not uncommon accident. Surgical treatment is always indicated and removal of the spleen is advisable if it is not obviously diseased. But if it be enlarged by long-standing disease suture or plugging of the rupture is to be recommended.

Thrombosis of the Splenic Vein sometimes occurs as a result of local pressure or sepsis and gives rise to enlargement of the organ and recurrent hæmatemesis—a condition suggesting and sometimes practically indistinguishable from splenic anæmia. Splenectomy is the proper treatment if the patient can stand the operation.

Abscess of the Spleen demands appropriate surgical treatment unless it occurs as a part of a general pyæmia, in which case local interference will not be adopted unless the general condition of the patient permits operation and encourages hope of recovery.

Primary Tuberculosis of the Spleen occasionally occurs and may cause massive enlargement. Good results following splenectomy have been recorded, but in all cases, whether operation is justifiable or not, general treatment should be carried out along the lines appropriate for other cases of tuberculosis.

New Growths and Cysts (simple, dermoid or parasitic).—When a diagnosis of primary splenic tumour can be made splenectomy is indicated. The event is a rare one and the exact nature of the lesion cannot always be determined before operation.

A. E. S.

DISEASES OF THE LYMPH GLANDS AND THYMUS

Acute Lymphadenitis.—Since this condition is the result of the transmission of organisms by lymph coming from an infected wound, the

primary focus of infection must be carefully looked for and when found appropriately treated. It sometimes happens that the glandular enlargement only appears after the primary infected wound has completely healed, but in these cases a scar is frequently to be found somewhere within the lymph area drained by the gland. Where the primary wound can be found it should be carefully cleansed, opened if pus be present, and dressed antiseptically. If on the fingers it is wise to avoid carbolic dressings, since if these be kept continually applied there is considerable risk of gangrene supervening. Most of the cases of gangrene following the use of carbolic acid dressings have occurred where weak solutions of 1 in 50 or 1 in 100 have been kept in contact with wounds overnight, the anæsthetic properties of the carbolic acid giving the patient no warning of the serious change that is occurring.

Glycerine of belladonna should be painted over the inflamed glands and hot fomentations applied, in this way not only will pain be relieved, but the resulting hyperæmia will lead to flooding of the tissues with opsonins and leucocytes. Where necessary a splint may be applied if rest cannot otherwise be ensured. As an alternative treatment passive hyperæmia may be induced by the application of a Bier's bandage—in those cases where the anatomical position of the inflamed gland allows of such a procedure—or Klapp's suction bell may be employed.

The exhibition of a saline purge and a tonic mixture will constitute all that is usually required in the way of general treatment.

If *suppuration* has occurred an incision should be made in the line of cleavage of the skin overlying the gland and the abscess opened. Hilton's method (*i. e.* the insertion of a pair of dressing forceps and opening the blades to secure free evacuation without the danger of wounding large vessels) may be of use where the glands are situated deeply in regions such as the neck or axilla; but if any of the gland remain it is wise to remove this entirely, since multiple foci of suppuration are frequently present in such residual portions of gland and considerable delay in healing will otherwise occur. For this purpose a finger or sharp spoon is all that is necessary, and a drainage tube should be inserted for a day or two.

The treatment of bubo is considered under the heading of *Venereal Lymphadenitis* (*vide infra*).

Venereal Lymphadenitis.—1. Glandular enlargement may be regarded as an almost constant phenomenon in primary and secondary syphilis; it is rarely met with in the tertiary stage of the disease. Suppuration does not occur unless in the primary stage some pyogenic organism in addition to the spirochæte gains access to the part. General anti-syphilitic treatment must be instituted, but no local treatment is called for.

2. A bubo, secondary to a soft sore, usually shows itself about fourteen days after the appearance of the sore, and unless treatment on definite lines is instituted *suppuration* is not likely to be long delayed.

(*a*) Where in the *early stages* inflammation is not acute, rest, with the application of a pad and firm Spica bandage is all that is requisite.

(*b*) Where *softening* of the glandular swelling threatens excision of the affected group of glands is better treatment than incision. Care must be taken to remove sufficient of the surrounding subcutaneous tissue to ensure against injury to the gland, otherwise healing by first intention is not likely to occur.

(*c*) Where an *abscess* is already present the best results follow the use of a flushing curette introduced through a small incision. Thorough flushing with a 1 in 4000 corrosive sublimate solution must be followed by scraping away the remains of the gland and the introduction of iodoform emulsion into the abscess cavity. Free incision is to be avoided as it is likely to be followed by the formation of an indolent ulcer.

3. A bubo occasionally occurs in the course of gonorrhœa, the local treatment differs in no way from that of acute adenitis ending in suppuration (*q. v.*).

Chronic Lymphadenitis results where long-continued toxic absorption or microbic infection is taking place. Here also a careful search must be instituted for the primary focus. In hospital practice the presence of pediculi in the head is one of the most frequent causes of cervical adenitis. Examination of the throat for tonsillar enlargement and adenoids, and of the mouth for the presence of carious teeth, must never be omitted in cervical cases. Mr. Warwick James, from an extended experience in the dental department at Gt. Ormond Street, finds that cervical glands are palpable in all children, but when healthy they can only just be felt and are freely movable. When irritated by *toxic* products they become enlarged and soft, but usually remain movable, and are only slightly, if at all tender. If definitely infected by *organisms*, they are tender, more or less fixed (periadenitis), and perhaps show softening at one point. After removal of the teeth in these cases and cleansing of the mouth the glands undergo contraction and remain as small firm nodules. Tubercle bacilli appear to be able to flourish in glands whose resistance has thus been lowered by chronic infection. Should enlargement of glands persist after removal of the primary focus of infection the possibility of tuberculosis must not be lost sight of.

Where the primary source of infection can be found, its removal is usually attended by more

or less gradual subsidence of the glandular enlargement and no local treatment directed to the glands is necessary. If an ulcer of the skin or dermatitis is found it must receive appropriate treatment.

Since secondary tuberculous infection is likely to occur in chronic cases of inflammatory enlargement, should the glands show no tendency to subside, or worse still, go on increasing in size, the more serious condition must be suspected, and suitable measures carried out for its treatment (*vide infra*).

It is not always easy to detect suppuration where glands are deeply placed, such as when lying beneath the sternomastoid, but if the patient be kept under close observation room for doubt cannot long exist.

Tuberculous Lymphadenitis is one of the most common of the chronic affections of childhood. The disease may affect any group of glands, but most commonly involves the bronchial and mesenteric groups among the more deeply seated glands, the cervical among the more superficial ones. Seeing that the organism obtained from affected glands is almost always of the bovine variety, infected *milk* must be regarded as the chief source of the disease. For this reason milk from tuberculin-tested cows, where such is available, should alone be used. When this cannot be obtained, all milk should be pasteurised or boiled, but the decrease in nutritive value which these methods entail renders such milk a less efficient substitute.

There is little doubt that in cases of tuberculosis of the cervical glands infection occurs through the tonsils and nasal part of the pharynx. Mr. Sampson Handley has suggested that much might be done to diminish the likelihood of infection if a practice were made, in the case of all town-bred children, of washing out the nasal part of the pharynx daily with a weak antiseptic. A fountain-pen filler forms an admirable means of introducing half a dozen drops or so of a weak solution of glycothymoline into each nostril night and morning. If the tonsils are enlarged they should be painted with a weak solution of iodine (0·5 per cent. solution).

While tuberculous cervical glands remain small, isolated and mobile no surgical interference is essential. But where signs of matting of the glands (periadenitis) or any tendency to softening is present, or where the overlying skin is becoming inflamed, surgical intervention can rarely be safely delayed.

In the earlier stages medical treatment will consist in placing the child in the best hygienic surroundings and, as regards locality, Margate and Ramsgate have a well-earned reputation. Sea air is not, however, essential, and children do very well in elevated open country. Internally the pharmacopœial Syrupus Ferri Iodidi is often of the greatest value, and doses of 20–30 min. may be given in a little water three times a day to a child of five. If the iron produce constipation, or the child is poorly nourished, one or two tablespoonfuls of cod-liver oil should be given morning and night in addition. There can now be obtained a crystalline preparation of malt extract and iodide of iron which is especially useful in cases of this kind. Arsenic in small doses (Liq. Arsenicalis 1–3 min.) either given alone or in conjunction with the iodide or phosphate of iron is often of the greatest value. Local applications such as iodine or hot fomentations to the affected glands are on the whole best avoided; they frequently appear to hasten softening. It is well to inform ignorant mothers and nurses not to handle or rub the swellings. If the enlarged glands are situated in a part like the groin, where they are exposed to considerable movement, rest must be enjoined, or secured where necessary by means of a splint and bandage.

In the early stages tuberculin has been largely employed apparently with a certain measure of success. In the later stages of the disease, where the glands lying in condensed fibrous tissue may be undergoing central caseation, the use of tuberculin cannot be defended. In these cases it is impossible for the protective substances formed in the body to reach the bacilli within the diseased gland.

Koch's New Tuberculin is the form usually employed. Either the human (T. R.) or the bovine (P. T. R.) variety may be used. The initial dose should be about $\frac{1}{100,000}$ c.c. T. R. ($\frac{1}{50,000}$ mg. solid substance), which is given hypodermically in isotonic solution. If the opsonic index is not determined it is usual to repeat the dose after eight days, and if after three injections no improvement results, the bovine tuberculin, P. T. R., may be substituted. The dose is gradually increased (controlled by temperature, pulse-rate and a consideration of constitutional symptoms) till something like $\frac{1}{1000}$ c.c. ($\frac{1}{500}$ mg. solid substance) is reached. By some vaccinists the dose is increased till in the case of an adult as much as 20 mg. is given.

Operation will be indicated in cases where matting of the glands has occurred and where suppuration threatens or is already present. Not only should all the enlarged glands be removed, but the whole layer of fat and fascia in which they are lying should be resected, as in this way alone can the surgeon ensure complete removal of infected, though not visibly tuberculous, glands. The operation is often one of some difficulty; it always involves opening the carotid sheath if carried out on the lines indicated, while any but a practised surgeon runs considerable risk of injuring the accessory nerve, which may escape recognition

lying embedded, as is so frequent in these cases, in a dense mass of fibrous tissue or of glands.

Hodgkin's Disease.—The exact nature of this disease still remains undetermined. Evidence is not wanting to show that it may follow repeated or chronic infection. It is, therefore, the duty of the medical attendant to seek diligently for any local source of infection. As the glandular enlargement usually first shows itself in the neck, a most careful examination of the mouth, nose and pharynx should never be omitted, and any infective focus must receive immediate attention. Should the disease when the patient is first seen be limited to one group of glands surgical removal of the glands in question should in addition be advocated. In some of the cases thus treated the disease appears to have undergone partial arrest, in others there has been no recurrence for several years. Surgical interference cannot be recommended where there is definite evidence of constitutional disturbance; hence operation is negatived—save for the relief of pressure—where there exist multiple glandular tumours, splenic enlargement, fever or severe anæmia. Of the remedial agents available in the treatment of this disease arsenic is probably the only one worthy of serious consideration. Whether it acts by attacking the infecting organism (if such exist) or by increasing the nutrition, and hence the resistance, of the tissues can only be conjectured. Fowler's solution is the form in which the drug is usually administered. Beginning with 3 min. three times a day after meals, the drug may be gradually increased till toxic effects as evidenced by itching of the eyes, silver furring of the tongue, garlic odour of the breath, or epigastric discomfort be noticed. Great diminution in the size of the glandular swellings sometimes occurs after the use of even such small doses of atoxyl as $\frac{1}{2}$ gr. twice weekly. Care must be taken not to " push " the dose of the organic arsenical compounds, since, unless due caution and discrimination be employed, optic atrophy may result. Should disturbance of vision be complained of, or any diminution of the visual field be recognised, the drug should be discontinued. Sodium cacodylate forms another useful vehicle for the exhibition of arsenic : it may be given once daily in $\frac{1}{2}$ gr. doses hypodermically. A remedy of which the writer has had no personal experience is phosphide of zinc which has been used with benefit in this disease; it is usually prescribed in pill form, the dose being $\frac{1}{20}$ gr. three times a day.

Remarkable results follow the application of X-ray treatment. Where the applications are persisted in the glandular swellings can often be kept under control, though it is doubtful if cases are actually permanently relieved.

It is too early yet to speak with any certainty of the effect of radium or salvarsan.

Lymphosarcoma. — Lymphosarcoma, when arising in lymph glands, usually affects the cervical or axillary group. So soon does the growth burst through the capsule and infiltrate surrounding structures that excision is rarely possible. Even where excision can be performed the outlook is very grave, as other glands soon show evidence of rapid enlargement. Little can be expected from the use of Coley's fluid in this dread disease. If it be decided to inject Coley's fluid (the Lister Institute supplies new Coley's fluid in 2 c.c. phials) it is usual to start with doses of $\frac{1}{4}$ or $\frac{1}{2}$ min. diluted with sterile distilled water. Slight malaise may follow the injection, but in susceptible patients a rigor and a rapid rise of temperature to 104° may occur. If there is no definite reaction the dose is repeated the following day, and the dose is increased by $\frac{1}{2}$ min. a day till a reaction occurs. From this point onwards the dose must be governed by the temperature, the object being to get a definite rise of temperature without serious constitutional disturbance. The maximum dose is rarely carried beyond 10 or 15 min. and treatment is usually continued until it is clear that no improvement is taking place or till the swelling disappears. The best results obtained with Coley's fluid have been in cases of spindle-celled sarcomas.

Several cases have been reported in which beneficial results have followed the use of radium. The best results are obtained where radium is buried within the growth for twenty-four hours.

In the late stages of the disease anodynes such as aspirin (15 gr.), phenacetin (5–10 gr.), or morphia ($\frac{1}{4}-\frac{1}{2}$ gr.) are necessary for the alleviation of pain.

Diseases of the Thymus Gland.—Almost the only disease of the thymus gland (if indeed the expression may be allowed) which is likely to benefit from medical treatment is the so-called status lymphaticus or lymphatism. The disease is more correctly regarded as one in which there is an overgrowth of lymph tissue throughout the body and in this overgrowth the thymus participates. The disease derives its chief interest from the startlingly sudden death to which its victims are liable if subjected to the most trifling operation or accident. Hence the recognition of such cases becomes of paramount importance.

Children suffering from lymphatism are usually pale and flabby. The tonsils are frequently enlarged and adenoids are likely to be present. A mild degree of rickets is not infrequently to be detected. The lymph tissue throughout the body is increased, but since the superficial lymph glands rarely show

any noticeable enlargement the disease is rarely diagnosed with certainty during life. In some cases the thyreoid gland is increased in size and in others a definite swelling in the suprasternal fossa, due to excessive enlargement of the thymus, has been noticed during expiration. X-ray examination may be of assistance in recognising this condition. An extensive area of dullness may be discovered over the upper part of the sternum and neighbouring portions of the chest wall, but it is almost impossible to distinguish such an area of dullness from that caused by tuberculous mediastinal glands. A somewhat more definite indication of the existence of an enlarged thymus is provided by the occurrence in such children of definite attacks of dyspnœa—the so-called thymic asthma.

If the condition is diagnosed, or strongly suspected, small doses of arsenic and iron should be given and any errors of diet corrected. If the child be rickety or syphilitic the underlying disease must be treated. Children tend to outgrow lymphatism, but as they appear to be unduly susceptible to infective diseases they should be kept as far as possible from the risk of infection. All operations save those of necessity must be avoided, and many deaths under anæsthesia, in the case of children, are assigned to this condition. Cold baths should not be allowed and excitement of all kinds is bad for the subjects of this malady. The use of fresh raw thymus gland obtained from sheep has been advocated, and as much as half an ounce of the extract of the gland in the form of tablets may be given to a child daily. Those who advocate this line of treatment argue that the thymus in undergoing hypertrophy is responding to some abnormal stimulus, and that if thymus extract be given in sufficient quantity the gland will gradually subside.

During an attack of thymic asthma, oxygen may be inspired and cardiac stimulants exhibited. In some cases intubation performed with a tube sufficiently long to reach the bifurcation of the trachea has been successfully performed, in others the thymus has been partly resected, or drawn forwards, and fixed to the fascia over the sternum.

Laxatives may be freely used. Some cases appear to have benefited by X-ray treatment.

It has been advised in the case of children subject to this distressing condition that the nurse should be warned not to allow the child to throw his head back and to do all in her power to prevent crying or screaming—truly a difficult task!—as anything which tends to increase the pressure which the gland exerts on surrounding structures, or which leads to congestion of the gland, may precipitate an attack. C. E. L.

TREATMENT OF DISEASES OF THE ALIMENTARY SYSTEM

DISEASES OF THE TEETH AND GUMS AS A FACTOR IN GASTRO-INTESTINAL DISEASES

Diseases of the gastro-intestinal canal which are secondary to diseases of the teeth and gums are, in most instances, due to infection caused by the continual swallowing of micro-organisms from septic conditions of the latter.

These conditions are—

1. *Pyorrhœa Alveolaris*, which is by far the most common.
2. *Advanced Caries*, especially when septic roots are present.
3. *Alveolar Abscesses*, in which the pus is draining into the mouth.
4. *Stomatitis*, due to general lack of oral cleanliness, especially with regard to dentures, etc.
5. *Certain irregularities of the teeth* such as overcrowding, which allow the lodgment and consequent decomposition of food.

1. **Pyorrhœa Alveolaris.**—The first thing to be done here is carefully to scale the teeth and then remove all the septic stumps and "dead" teeth. The "dead," or pulpless teeth, always remain a likely source of fresh infection. They have lost the blood supply to the pulp and can only receive a limited supply of nourishment from the partially destroyed periodontal membrane, consequently in the present state of our knowledge it is impossible to render them perfectly healthy. All gold crowns and bridges must be removed, as they almost invariably cause damage to the periodontal membrane. In considering the further treatment it is advisable to divide the cases into two classes—

(*a*) Those patients who are not as yet showing general symptoms.

(*b*) Those patients who, in a greater or less degree, are showing signs of toxæmia.

(1) In the first class a radiograph should be taken to ascertain the amount of rarefying osteitis present in the alveolar process, and the depth of the pockets round the teeth should be ascertained by a fine probe. The amount of pus that can be squeezed out of each pocket and the amount of gingivitis present should be noted.

By these means we can further subdivide this class into—

(i) Slight cases in which the amount of osteitis is small and the pockets shallow.

(ii) Advanced cases in which there is a con-

siderable amount of rarefying osteitis present and the pockets are deep.

In the slight cases conservative measures can be tried. It may be admitted at once that there is no known method of bringing about the reformation of the absorbed bone and so effecting a cure. All we can hope to do is to *arrest* the disease and prevent recurrence by getting rid of the pockets. Now considering that the disease is probably predisposed to by a loss of resisting power of the alveolar process due to our modern cooking and consequent lack of proper mastication, as pointed out by Mr. J. F. Colyer, the patient must be instructed to correct this as far as possible by living on fibrous foodstuffs requiring a certain amount of mastication, and this must be carefully and conscientiously performed. By this means an increased blood supply is brought to the alveolar process and its "tone," or resisting power, is increased. Further the patient should be instructed to carry out at least three times a day, and if possible before and after each meal, the following treatment: First to squeeze out the pus and debris from the pockets round each tooth by pressure between finger and thumb; then to wash his mouth out for two or three minutes with the following mouth-wash—

℞ Liquor Potassæ ʒ vi
Acidi Carbolici ʒ iv
Liquor Cocci ʒ ii
Aquam ad. ℥ viii

One teaspoonful to half a tumblerful of warm water. The object of the Liquor Potassæ is to dissolve the mucus and so allow the carbolic acid to act as an antiseptic. This having been done, the patient should carefully brush all surfaces of the teeth and gums, especially the latter, with a hard tooth-brush and soap, in order to scarify them, using an up and down, as well as a to and fro, movement. A powder should not be used, as it is liable to "cake" in the pockets and act as an irritant. Lastly, the mouth should be washed out with a hydrogen peroxide mouth-wash, using the 10 per cent. solution, for two or three minutes. The whole process should occupy about fifteen minutes.

The dental surgeon must assist the patient by keeping all the teeth very carefully scaled and polished, taking great care to injure the gingival margin as little as possible during the operation. All areas of stagnation, viz. places where, owing to the destruction of the interdental papillæ, food is very liable to lodge and decompose, must be carefully attended to. If the gum papillæ are soft and spongy they should be cut away with a pair of sharp curved scissors, and in the same way all "pockets" round the teeth must be removed. The importance of this cannot be too strongly insisted upon because if they are left they speedily become reinfected. Equally important is it to insist upon the patient breathing through the nose, experience having shown the impossibility of ever arresting the disease in mouth-breathers.

At the end of six months another radiograph should be taken to ascertain whether the disease has been arrested by these means. If it has the patient may retain his teeth; but only then under careful supervision, as there is always a strong tendency to recurrence. If the disease is still spreading, as shown by the extent of the rarefying osteitis, it must be treated as a severe case. In discussing the treatment of severe cases, in which there is no evidence of a general toxæmia, the question arises—is there any justification for condemning the remaining teeth? I agree with Mr. J. F. Colyer in thinking that there is, because, in the first place, the patient's resisting power may at any time become broken down by some other intercurrent disease, and that disease, plus the oral sepsis, may not improbably lead to serious, or even fatal, results; and in the second place, if the bony absorption is allowed to progress until the teeth drop out, there is practically no alveolar ridge left for the retention of dentures, whereas if they are extracted early a good ridge results to which dentures can be comfortably fitted. Granting the disease to be incurable, it is not wise to put off the wearing of dentures to the last possible moment and then find them always inefficient and uncomfortable because of the absence of a proper ridge. It is far wiser to anticipate their adoption by a few years, and by so doing make for efficiency.

(2) *Cases Showing General Toxæmia.* In these cases all the affected teeth should be removed as a general rule. Extensive extraction having been decided upon, the question arises—should all the teeth be removed at a single operation? When a large number of teeth are removed at one time there remains after the operation a large raw surface, through which septic absorption may take place. Cases have been reported in which death has followed from this cause a few days after the operation. When, however, one considers the large number of these operations which have been done, and the very few cases in which anything untoward has happened, it is clear that the risk is very small. Unfortunately very few dental surgeons at the present time make any attempt to cleanse the area of operation before operating. If all the tartar is removed carefully a few days before, and the gums, especially the spaces between the teeth, carefully painted with a 2 per cent. solution of iodine in rectified spirit immediately before the operation, the risk is reduced to a minimum. It would seem to be the best plan to remove all the teeth at one time

in those cases where the patient is dangerously ill from septic absorption. In such cases vaccines may be used to advantage for tiding the patient over the danger period—the ten days following the operation.

In cases where there is no such urgency, it is better to remove all the molars at the first operation and then a week later to insert dentures. When the first wounds have healed the incisors can be removed and replaced on the dentures, leaving the bicuspids to aid in their support until the patient is thoroughly accustomed to retaining them in position. The great advantage of this method is that the teeth standing when the dentures are first inserted give the correct bite.

The generally accepted view of the vaccine treatment of pyorrhœa alveolaris is that it merely deals with the symptoms due to the toxæmia; it does nothing to assist the cure of the disease itself; the pockets round the teeth and the areas of stagnation remain and quickly become reinfected. The rarefying osteitis is possibly checked during the period in which injections are being made, although there is as yet no direct evidence even of this. When the vaccine treatment is stopped, the rarefying osteitis certainly progresses with a return of the toxæmic symptoms.

The electrical, or ionic, treatment is also of little permanent use because though it may sterilise the pockets it does not get rid of them, and they invariably become reinfected.

2. **Advanced Caries.**—Here the unsaveable teeth must be removed and the saveable ones filled. "Collar" crowns should be avoided, as they almost invariably lead, sooner or later, to damage of the gingival margin and periodontal membrane. In adults all functionless (*i. e.* unopposed) teeth must be made functional by suitable dentures. In children, not only must all unsaveable teeth be removed, but their antagonists also. In a case, for instance, where the four lower molars are unsaveable, it is useless to leave the four upper. The loss of their antagonists has rendered them useless for masticating purposes. They consequently are no longer self-cleansed by the mastication of the fibrous foodstuffs and quickly become carious and gingivitis is set up around them.

3. **Alveolar Abscesses.**—If the tooth is unsaveable, it should be removed; if saveable, the abscess must be thoroughly opened up and drained.

4. **Stomatitis.**—The cause should be removed; a suitable mouth-wash prescribed, and the patient instructed in oral hygiene. (See *Stomatitis.*)

5. **Irregularities of the Teeth. Overcrowding.**—Here the alveolar process is not large enough to accommodate all the teeth properly in a regular arch. This is due very frequently to lack of development of the jaws owing to nasal obstruction, whereby one or more teeth are crowded out of the proper alignment, and form stagnation areas where food must lodge and decompose.

Treatment consists of either—

(*a*) Expansion of the arch.

(*b*) Extraction of the instanding teeth.

With regard to expansion, it must be remembered that the appliances used for this are liable merely to swing the teeth out on a point at their apices, so that if the arch is much expanded the articulation of the teeth is ruined. However, in suitable cases, expansion is the best method. When nasal obstruction is the cause, expansion of the jaws can be brought about by simply removing the obstruction and rendering the nasal cavities again functional. In severe cases, extraction is the only satisfactory method.

Finally dyspepsia may arise in patients with healthy mouths due to inefficient mastication, owing to the loss of several teeth. These teeth can be replaced by—

(*a*) Dentures.

(*b*) Bridges.

In favour of the first is the fact that they can be easily removed and cleaned.

In favour of the second is the fact that they are fixed and consequently preferred by many patients. They are, however, very difficult, if not impossible, to construct in such a way that they can be kept clean. Their use almost invariably leads, sooner or later, to chronic suppurative periodontitis (pyorrhœa alveolaris).

F. St. J. S.

STOMATITIS

The term stomatitis is very wide and indefinite. It includes an inflammation which may spread over the whole surface of the mucous membrane covering the gums and cheeks, or which may be more or less limited to the gingiva. In the former case it is generally acute, and is very much commoner in children than in adults. In the latter case it is generally chronic, is most common in adults, and is almost invariably associated with periodontal disease (see *Pyorrhœa Alveolaris*).

Stomatitis in children very commonly follows measles; in a large number of children examined by the writer, the great majority of those suffering from stomatitis had had measles.

Children with nasal obstruction, and who are consequently mouth-breathers, almost invariably suffer from stomatitis in a greater or less degree. It is also frequently associated with gastrointestinal trouble, or with dentition, when it is usually localised around the erupting tooth.

Stomatitis in very young children can often be traced to dirty feeding-bottles, or faulty

oral hygiene. In adults, a chronic form of stomatitis is often seen under artificial dentures, especially those made of red vulcanite. This is frequently due to lack of cleanliness, and quickly disappears when this is remedied and the plates left out a few days. In some cases, however, the writer has only been able to cure this condition by inserting a new denture made of black instead of red vulcanite.

Several forms of stomatitis have been described, but before considering the treatment of these in detail a few general remarks should be made.

In treating stomatitis it is of the utmost importance that proper nasal breathing should be established. Any nasal obstruction, if present, must be removed. If this is not done an acute case may not only become chronic and very resistent to treatment, but the inflammation may spread to the periodontal membrane setting up chronic suppurative periodontitis (pyorrhœa alveolaris) with all its attendant evils both local and general.

All septic teeth which cannot be made healthy must be removed. Gastro-intestinal trouble must be treated.

1. **Catarrhal Stomatitis.**
2. **Aphthous Stomatitis.**
3. **Ulcerative Stomatitis.**

The treatment of these three forms may be taken together. In young children the mouth should be carefully wiped round with glycerin of borax, applied on a piece of soft linen or lint which should afterwards be destroyed. In older children, and in adults, the mouth-wash recommended by Dr. Still is one of the most suitable—

℞ Pot. Chlorat. gr. vii ss
Boracis gr. x
Glycerin ʒ ss
Aq. Rosæ ad. ℥ i
As a mouth-wash.

Aphthæ or ulcers which persist may be swabbed over with a solution of silver nitrate 5 gr. to the 1 oz., or pure silver nitrate may be applied. This is best done by heating the end of a blunt probe to redness, rubbing it over a stick of silver nitrate, and touching the ulcer with this after it has been allowed to cool.

Chlorate of potash internally is very beneficial. Children may be given 4–8 grs. according to age. Adults 10–15 grs.

A tonic may be advantageously prescribed with this, such as—

℞ Tinct. Ferri Perchloridi ʒ ii
Pot. Chlorat. gr. lxxx
Spiritus Chloroformi ♏ lxxx
Glycerin ʒ iii
Aquam ad. ℥ viii.

Two tablespoonfuls to be taken every four hours.

A purge should be given.

4. **Gangrenous Stomatitis or Cancrum Oris.**—The treatment here must be prompt and energetic if the child's life is to be saved. The whole of the affected area must be thoroughly and completely removed until healthy bleeding tissue is reached. The raw surface must then be thoroughly cauterised, either by strong nitric acid, pure carbolic or the actual cautery.

5. **Parasitic Stomatitis (Thrush).**—The mouth should be carefully wiped round with a piece of lint dipped in glycerin of borax after each meal. An alkaline mouth-wash should be prescribed—

℞ Acidi Carbolici ʒ iv
Liquor Potassii ʒ vi
Aquam ad. ℥ viii.

One teaspoonful to half a tumblerful of warm water as a mouth-wash frequently. In the case of a young child the mouth can be swabbed with a piece of cotton-wool dipped in this.

Chlorate of potash should be given internally.

It must be remembered that the disease is infectious, and all feeding-bottles must be carefully sterilised. The mother's nipples should be treated after each suckling with a mild antiseptic.

6. **Mercurial Stomatitis.**—An antiseptic mouth-wash should be prescribed. The drug should be discontinued until the local condition shows marked improvement. If the pain is severe Pulv. Opii Co. should be given at night.

F. St. J. S.

DISEASES OF THE SALIVARY GLANDS

Increase of Secretion.—This is due to a variety of causes, thus it may be (1) apparent in paralysis of the muscles of swallowing in septic tonsillitis and pharyngitis, with septic teeth and their results, and in the various forms of stomatitis—here the cause must be dealt with by appropriate means; (2) *Toxic* due to pilocarpine, mercurial poisoning and uræmia; (3) *reflex* in pregnancy and hysteria; it may even be a normal condition in children. Atropin is of real benefit in reflex salivation, a single hypodermic injection of $\frac{1}{100}$ gr. should be given rather than the continued administration of tincture of belladonna.

Decrease of Secretion may be (1) toxic in fevers, particularly typhoid—here mouth-washes containing lemon juice are indicated; (2) due to atropin poisoning. Here a dose of pilocarpine hypodermically acts well once the poison is discontinued, decreased secretion is frequently noticed in arterio-sclerosis, occurring in comparatively early life—its occurrence materially increases the gravity of the prognosis. In this connection the condition described by the

late Sir Jonathan Hutchinson as "xerostomia" may be noticed; it is very common in women, and as resistant to treatment. Little is known of its causes. Pilocarpine or the galvanic current would appear to be the only lines of treatment.

Inflammation. Acute Primary Epidemic-parotitis.—The general treatment of this condition will be found under infective fevers. Attention may be here directed to the very remarkable results of the inunction of iodex (Pigm. Iodi M. and J.) on the affected glands. All swelling and signs of inflammation are removed in about forty-eight hours by gentle inunction every two hours. Nothing definite is known as to any alteration in the period of infectivity by this treatment. A modified Trendelenburg position has been suggested with a view to avoiding "sympathetic" inflammation of the reproductive glands.

Secondary Acute Parotitis.—This is known to be associated with septic infections below the diaphragm. With more active surgical intervention its frequency is diminishing, the early occurrence of suppuration as well as the frequency of a burrowing outside the "parotid fossa" should be remembered. A very early incision will not usually be regretted. On the other hand, many hold that it is always secondary to a dry infected mouth whether the primary cause of infection is above or below the diaphragm, also that many resolve without incision.

Chronic Parotitis is usually caused by stones in the ducts, which should be surgically dealt with. In addition to stones, a chronic fibrinous inflammation of the ducts has been described. It is worthy of note that tuberculosis of the salivary glands is of extreme rarity (this must not be confounded with tuberculosis of lymph glands in their neighbourhood).

Symmetrical Enlargement of Lacrimal and Salivary Glands.—This has been described as "Mikulicx's disease." It would appear to be of very complex nature, and due to increase of lymph tissue, possibly a lymphoid hyperplasia. X-rays together with arsenic and iodides in full doses at the same time have given good results.

Occasional Enlargement of Salivary Glands.—This is of quite frequent occurrence, especially in the submaxillary gland; it is usually observed in a single gland. It is said to be usually caused by calculus in the duct, but the author has seen no less than nine cases in children under twelve, where no calculus or other cause of obstruction could be found. In all these cases the intermittent swelling disappeared ultimately.

Salivary Calculi.—Symptoms of their presence closely resemble the above. Swelling of the gland (usually the submaxillary) occurs immediately after a meal; it is usually painful (salivary colic), and the swelling slowly disappears, returning after the next meal taken. The calculus is usually single, and can be felt 10–20 mm. from the submaxillary caruncle. They are usually single and are probably due to bacterial infection as in the case of gall stones. They can be readily cut down on and removed.

Ranula.—This cystic swelling in the floor of the mouth is usually due to cystic degeneration of one of the glands in the floor of the mouth. When congenital it is usually due to imperfect development of the duct of the submaxillary or sublingual gland. Treatment is by cutting down on the cyst, and removing as much of the cyst wall as possible, the rest being left to granulate.

Growths.—So-called "simple" or mixed tumour. Seventy-five per cent. of all these occur in the parotid. They are really endotheliomata, developing from branchial rests. It is to be remembered that sooner or later the great majority of these tumours take on malignant growth—thus they are dangerous, and their treatment should be removal as early as possible.

Growths (Malignant).—In these growths the facial nerve is usually early involved, and there are symptoms of various obstruction in contradistinction to the innocent growths. For such growths the whole parotid gland has been frequently removed together with the lymph glands in the upper part of the neck—such an operation is obviously a formidable one, and in my opinion it should not be undertaken except in very early cases where the diagnosis has been confirmed on incision by an immediate microscope section. In all such cases, the prophylactic use of radium and X-rays is to be recommended often, and the same means are all that is left to us in the inoperable cases.

Salivary Fistulæ.—These are usually the result of injury. If they occur in the glands themselves, they usually close spontaneously, if not the use of the cautery will usually rapidly effect a cure. On the other hand, a fistula of the parotid duct on to the face has very little tendency to close spontaneously. Here the best treatment is not to waste time, but to slit up the duct freely into the cavity of the mouth and make an internal fistula out of it.

Ludwig's Angina, though hardly an infection of the salivary glands, is usually an acute cellulitis of the floor of the mouth, originating in the submaxillary lymph glands. Its causes are manifold—suffice to say that this condition may result from any septic wound in the mouth, pharynx and upper air-passages. By far the most frequent organism is some form of streptococcus, usually the streptococcus longus; the pneumococcus and the B. diphtheriæ are also frequently found. The dangers of what is described as a "collar-swelling" in the neck cannot be exaggerated, and the onset of acute œdema of the larynx has usually no definite relation to the amount or duration of the external swelling

—early incisions should be the invariable rule if there is any reason to fear this condition—it is far better to incise a collection of inflammatory glands than run any risk of leaving Ludwig's angina to pursue its course—a cultivation should be taken and an attempt made to procure a vaccine for future use.

Meanwhile the wounds should be left open. I have recently in this, and other septic conditions smeared the whole raw surface freely with "Iodex," and have had admirable results. It is obvious that skilled nursing should be at hand in all such cases, until the inflammatory symptoms are at an end, and that tracheotomy should be at once resorted to on the *very slightest* respiratory difficulty. At the risk of repetition it cannot be too strongly insisted on that there should not be any hesitation or delay in performing tracheotomy even though the difficulty in respiration seems but trivial. J. K. M.

DISEASES OF THE TONSILS

Removal of Tonsils

When from adequate reasons it is decided that the tonsils should be removed, it is axiomatic that the more completely this is carried out the better, if recurrence of symptoms is to be avoided. This does not necessarily mean that a severe dissecting operation is a *sine quâ non*. Though the old-fashioned operation of tonsillotomy by means of a *sharp* guillotine frequently failed to remove sufficient to prevent recurrence of symptoms, and rarely removed more than nine-tenths of the tonsil, it does not follow that operation with the guillotine alone should be regarded as obsolete, and that all tonsillectomies in future should include partial dissection; for it is abundantly proved that with a *slightly blunt* guillotine alone a complete extra-capsular excision of the entire tonsil can be frequently, and even usually, accomplished by an expert operator. In *buried tonsils with septic crypts*, and in tonsils where the pillars and plica are adherent, complete enucleation by a dissecting operation for freeing the pillars before applying the snare or the blunt guillotine or using the bistoury is usually essential.

The various methods of removal at our disposal may be summarised as follows—

1. With *sharp* guillotine plus external digital compression below the angle of the jaw carried out by the anæsthetist or by an assistant. This method is often inefficient.
2. Blunt guillotine plus external compression.
3. The foregoing combined with traction through the ring of the guillotine by the vulsellum.
4. Blunt guillotine plus internal digital compression at the anterior pillar of the fauces made by the operator in order to squeeze the large tonsil through the smaller ring; to this external compression can be added. This method, originated by Whillis, is the method of choice with a large number of experts at the present day. Sluder's method is somewhat similar. The shaft of the guillotine should be directed towards the tonsil from the angle of the mouth of the opposite side, and the ring of the instrument used as a raspatory to detach the gland from the posterior pillar and, with its capsule, from the tonsillar bed in a direction upwards and forwards, so as to bring it against the eminence on the lower jaw produced by the last molar tooth; the blade is then driven home. The only disadvantage in this method (Sluder's) is that the anterior pillar is usually slightly wounded, and Peters therefore prefers to make two cuts with the guillotine, the first a slight one to detach the tonsil from the anterior pillar; the cutting blade is then readjusted and the ring made to displace the tonsil further upwards and forwards before the second stroke, which removes the whole tonsil with its capsule, is carried out.
5. Blunt guillotine plus internal or external compression, or both plus vulsellum.
6. Snare, plus compression, plus vulsellum.
7. Dissection, *i. e.* instrumental separation of superior pole of the tonsil and of the adherent pillars, aided by traction with vulsellum, and followed by attempted complete enucleation with finger.
8. Dissection with the aid of dissector and vulsellum, as in the foregoing, followed by complete removal with a blunt guillotine; digital compression can be employed to supplement traction with the vulsellum. This is the operation favoured by many specialists (when dissection is indicated) as being almost bloodless in many instances. It is an operation which is only suitable for experienced and expert handicraftsmen, and has the disadvantage of requiring a fairly deep anæsthesia.
9. A snare can be substituted for the guillotine in the last method (No. 8).

When the tonsil, after any of the above operations, is still adherent at one spot and the instrument is "held," the finger is used as a separator and swept round the bed of the tonsil.

Of these operations, 2 and 4 are the favourite procedures, and by such simple means the majority of enlarged tonsils can be satisfactorily removed, provided a not too sharp guillotine of sufficiently small size be employed and the operator is reasonably expert, more especially in threading the tonsil into the instrument from the inferior pole.

Many experts, however, prefer to carry out tonsillectomy by means of a vulsellum and snare, and claim that there is less trauma and hæmorrhage.

For adherent and for buried tonsils a dissecting operation such as 8 or 9 should be resorted to in order to effect a complete excision

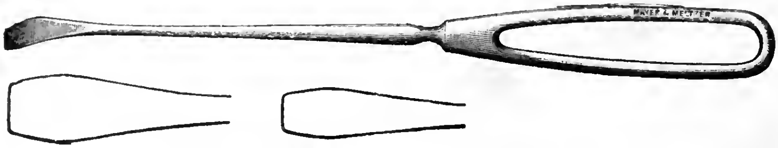

Fig. 1.—Dan McKenzie's Tonsil Dissector.

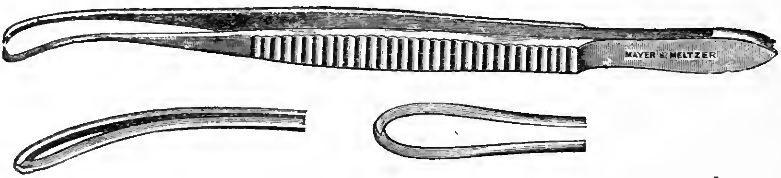

Fig 2 —Hope's Tonsil Forceps, which can be used either as a tenaculum or as a dissector.

of the tonsil along with its capsule. It must be remembered that there is often greater inflammatory reaction and increased liability to hæmorrhage after dissection operations,

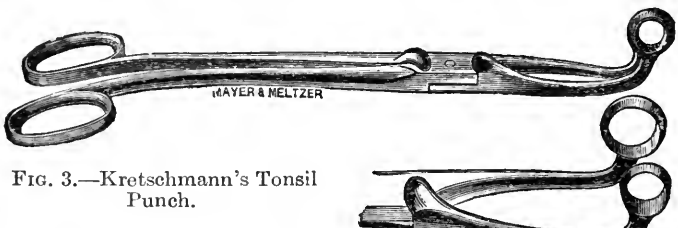

Fig. 3.—Kretschmann's Tonsil Punch.

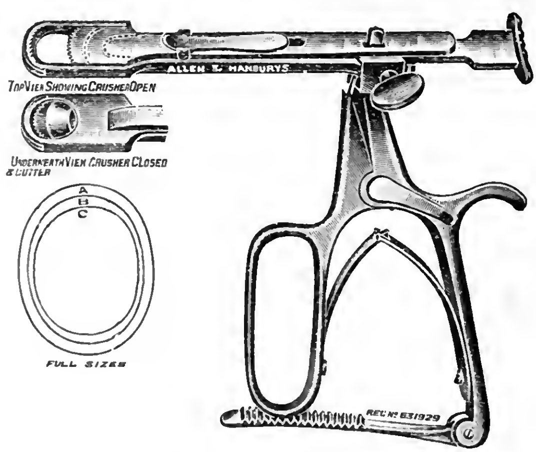

Fig. 4.—Elphick's Hæmastatic Guillotine.

and with the capsular barrier removed increased risk of infection of the adjacent lymphatics. There is much difference of opinion as to the employment of the knife or of a blunt dissector for detaching the pillars; the advantage of a blunt instrument is that it is also available for freeing the superior pole of the tonsil containing the *crypta magna* (tonsillar recess).

10. Removal of the parenchyma, leaving the capsule intact, by *morcellement*, accomplished either by digital scarification or by punch forceps, is mentioned only to be condemned if carried out as a complete operation, though partial *morcellement* with Kretschmann's punch is justifiable for the removal of small portions of tonsillar tissue left behind after other operative methods, especially after attempted enucleation by finger, or by dissection, in which the tonsils turn out to be very friable.

The position of the patient, whether sitting in a chair or lying in the extended position on a table, the choice of anæsthetic and the question of long or short anæsthesia, are points on which it is impossible to dogmatise in view of the divergent opinions and practice obtaining among experts. Open chloroform anæsthesia on a table or couch is essential in the case of slow or only moderately experienced operators, when any operation which includes dissection is about to be carried out.

As regards tonsillectomes, the modifications of McKenzie's guillotine still hold the field in this country, Hugh Jones's pattern and also Heath's being largely used. I sometimes employ a McKenzie guillotine with a lifting fork attached for buried tonsils. Ballinger's tonsillectome is much used in America, and after two years' experience with it I can recommend it as a very efficient one-handed instrument, though rather complicated for rapid cleansing in hospital practice. Elphick has recently modified Ballinger's instrument by strengthening the crushing blade and adding a sharp-edged blade to detach the tonsil from the crushed stump, thus securing hæmostasis.

W. H.

SPECIAL TOPICAL METHODS OF TREATMENT OF THE FAUCES AND PHARYNX

Whilst general medical treatment alone suffices in some diseases of these regions, and is indicated

in association with local measures, in many others the modern tendency is in the direction of increased refinement in and the wider application of local measures. The methods at our disposal include the employment of—

1. Watery fluids as gargles, sprays and douches.
2. Oily fluids as sprays.
3. Pigments.
4. Lozenges and pastilles.
5. Insufflation of powders.
6. Inhalations either in the cold and dry, or in the hot or vaporised, form.
7. The application of heat and cold.
8. Cauterising agents.
9. Electrical methods, including faradism, galvanism, the sinusoidal or wave current, ionisation, diathermy and galvano-cauterisation.
10. Ray treatment, either by the Roentgen rays or by radio-active substances such as radium salts and thorium.

Watery Fluids

Gargles.—Cleansing, astringent, stimulating and anodyne solutions are largely prescribed. Gargling, however, is not a very efficient method for obtaining the maximum local application of any therapeutic agent to the pharynx, and is oftener than not on a par with using a mouth-wash, a useful enough measure of course as such. In acute conditions it is painful and often impossible to gargle, and in subacute inflammations the solution rarely passes beyond the fauces. Gargling, however, with astringents, *e. g.* solutions of alum and even with cold water in chronic relaxed and paretic conditions of the palate, is often of service when the patient has acquired the knack of carrying it out efficiently.

Coarse Sprays and Douches.—Alkaline lotions for clearing the fauces and pharynx of thick mucus or adherent false membrane and sloughs is best carried out by a coarse atomiser, the nozzle of which is movable so that the stream can be applied in various directions when the nozzle is inserted well into the throat; the tongue may require depression. A stronger impact can be obtained by using a syringe or syphon douche with a suitable nozzle; this method is especially indicated in the naso-pharynx, but is also useful elsewhere when the atomiser proves inefficient.

The following watery solutions can be used either as sprays, douches or gargles—

Detergent and Alkaline.

℞ Pot. Chlorat. (vel. Sodii Chloridi vel. Ammon. Chloridi) ℥ ss
Boracis ℥ ss
Sod. Bicarb. ℥ ss
Sacch. Alb. ℥ i

One dr. to be dissolved in half a tumbler of cold water. Warm water can be used for gargling and douching.

(This is the well-known "Pulv. Chlor. Co." of the Central London Throat and Ear Hospital Pharmacopœia.)

℞ Sod. Bicarb. gr. xv
Boracis gr. xv
Acidi Carbolici gr. iv
Glycerini ♏ xlv
Aq. ad ℥ i.

(This is the Nebula Alkalina of the Throat Hospital Pharmacopœia.)

Astringent.—The following quantities represent the dose to an ounce of water in each case—

Alum gr. v–xv
Sulphate of copper gr. v
Chloride of zinc gr. x–xx
Sulphate of zinc gr. x–xx
Tannic acid gr. v–x.

Lotio Krameriæ Co.

℞ Tr. Krameriæ ♏ x
Tr. Myrrh ♏ x
Tr. Lavand. Co. ♏ v
Glycerini Borici ʒ i
Aq. ad ℥ i.

An astringent and sedative mouth-wash and gargle.

Lotio Boracis Co.

℞ Boracis gr. xxv
Tr. Myrrh ♏ xxv
Glycerini ♏ xxv
Aq. ad ℥ i.

Sedative.—

Chlorate of Potash gr. x–xx Borax gr. x–xx Glycothymoline ʒ i–iii Listerine ʒ i–iii Dilute Hydrocyanic Acid ♏ iii	to the ounce of water in each case.

The last is useful in cough of tuberculosis—only about ½ dr. to be used at a time as a spray.

℞ Lotio Nigra ℥ ss
Pot. Chloratis gr. x
Aq. ad ℥ i.

Useful as a sedative and antiseptic mouth-wash and gargle in syphilis.

Antiseptic Mouth-washes, Gargles and Douches.

Resorcin gr. x–xx Permanganate of potash gr. ¼–i Sanitas ♏ xxx Biniodide of mercury gr. ⅛ Perchloride of mercury gr. ss Salicylate of soda gr. x	to the ounce of water in each case.

℞ Sodii Benzoatis ʒ ii
Resorcini ʒ ss
Phenozoni ʒ i
Glycerini ad ℥ viii.

A teaspoonful in half a tumbler of tepid water. An antiseptic and soothing gargle or douche.

℞ Acidi Salicylici ʒ i
Sodii Chloridi ʒ x
Sodii Bicarbonatis ℥ ii ss.

Half a teaspoonful in a tumbler of tepid water; in septic and rheumatic tonsillitis as a douche.

Resolvent.—To facilitate the detachment of false membrane and sloughs any of the following sprays may prove useful—

Liquor Calcis.
Lactic acid ʒ i–ii to the ounce of water.
Salicylate of soda gr. xx to the ounce of water.
Papain gr. x–xx to the ounce of water.

Oily Solutions

These can be used either by means of a special atomiser or with a brush.

℞ Menthol gr. x ad gr. xx
Thymol gr. i ad gr. v
Eucalyptol ♏ i ad ♏ v
Parolein ad ℥ i.

This strong menthol spray should only be employed as a stimulant and sedative in atrophic conditions. In sub-acute tonsillitis and pharyngitis 2 to 5 gr. of menthol to the ounce is usually of sufficient strength.

℞ Camphor-menthol gr. x
Parolein ℥ i.

A sedative in acute inflammation of the fauces and pharynx.

℞ Menthol gr. v
Cocaine gr. xx
Ac. Oleic ♏ xv
Parolein ad ℥ i.

Sedative.

Pigments

Guaiacol (pure).

This should be applied only after cocainisation by the practitioner himself. Occasionally useful for aborting an acute tonsillitis.

℞ Guaiacol ʒ ii
Glycerinum ad ℥ i.

This can be applied by the patient to the tonsils thrice at intervals of two hours to endeavour to abort an acute tonsillitis with lacunar exudations (so-called follicular tonsillitis).

The following is the formula of the well-known Mandl's solution, which, however, is not so much in vogue as formerly.

℞ Iodi Puri gr. v ad gr. x
Pot. Iodidi gr. xx vel. q. s.
Ol. Menth. Pip. ♏ v
Glycerini ℥ i.

Stimulant and antiseptic in atrophic pharyngitis; it is also used to cut short sloughing and to stimulate healing after tonsillectomy in debilitated subjects. Its employment for subacute and chronic hypertrophic pharyngitis in voice users has been largely given up in favour of alkaline sprays and douches, and the milder application of atomised menthol.

Deliquesced Chromic Acid.—Applied pure as a caustic and stimulant in syphilitic ulcers. Since the introduction of salvarsan the use of this and other caustics has been largely abandoned.

Lactic Acid.—Applied pure as a caustic to ulcers. Twenty to fifty per cent. solutions were formerly much used in diphtheria and in tuberculosis; since the introduction of therapeutic inoculation methods, however, such applications are rarely made.

Boroglyceride.—Applied either pure or diluted with an equal quantity of glycerine in septic ulcerative conditions.

℞ Resorcin ʒ i ss
Glycerini Boracis ℥ i.

Antiseptic and Astringent.

℞ Chloride of zinc gr. xv–xxx to the ounce of water
Sulphate of zinc ʒ i to the ounce of water.

Local Anæsthetics

℞ Cocainæ Hydrochloridi gr. xxiv ad xcvi
Acidi Salicylici gr. ss
Aq. Destill. ad ℥ i.

These solutions, varying from 5 to 20 per cent., should be applied by the surgeon with a brush to produce local anodyne action in painful conditions or for local anæsthetic purposes in endoscopic and surgical measures. Twenty-five gr. of suprarenal extract (Merck) can be added if a marked ischæmic effect is desired. A smaller quantity of one of the numerous forms of suprarenal gland extract or its synthetic equivalent is useful for mitigating the toxic effect of cocaine by limiting its absorption into the general circulation.

℞ Cocainæ Hydrochloridi gr. xx vel. q. s.
Phenozoni gr. xl
Liq. Thymol Alcoholici ♏ ii
Aq. Destill. ad. ℥ i.

The phenazone is said to increase the anæsthetic action and the thymol solution tends to preserve the solution, like the salicylic acid in the preceding formula.

Eucaine can be substituted for cocaine in the above two formulæ, but it is not so readily soluble in water, so that it is only suitable for 5 to 8 per cent solutions.

Submucous Injections

Ampoules containing a 2 per cent. solution of novocaine, together with suprarenin (synthetic), are sold, and are useful for minor operations, *e. g.*

for injecting the pillars of the tonsils previous to tonsillectomy without a general anæsthetic. Synthetic suprarenin possesses the advantage over the animal extract in that it can be boiled if necessary. The composition of an ampoule is as follows—

℞ Novocainæ gm. 0·1
Suprarenin Boratis gm. 0·00045
Sodii Chloridi gm. 0·045
Aq. Destill. ad c.c. v.

Pastes

The only form of paste included in the Throat Hospital Pharmacopœia is Pasta Acidi Tannici, which is made by mixing together tannic acid 3 parts, and gallic acid 1 part, and adding a few drops of water, and kneading till a firm mass is formed. A portion about the size of a marble is then held against the bleeding surface of the tonsil to arrest severe hæmorrhage after tonsillotomy. Lennox Browne recommended the sipping of a thick saturated solution in which ½ oz. of the above powder is dissolved in 1 oz. of water.

A thick paste of bismuth oxychloride to which 5 to 10 gr. or more of chloretone or of orthoform has been added to 1 oz. of paste is useful in painful ulcerating conditions in the throat and gullet, as when the mass is swallowed much of it tends to stick for a considerable time on the ulcerated areas. The coating of bismuth is sedative in itself apart from the added analgesic powders.

Lozenges, Compressed Tablets and Pastilles

The lozenges and pastilles hereafter mentioned are chiefly of the composition set forth in the well-known Throat Hospital Pharmacopœia. These agents are admirably adapted for exercising a prolonged influence on the mouth, fauces and pharynx. Some of them, unfortunately, upset the appetite and digestion if taken with frequency. This applies not only to those containing morphia, but is a marked characteristic of the slowly dissolving lozenges and compressed tablets containing chlorate of potash, so largely prescribed. For rapid action pastilles made up with a glyco-gelatine base are to be preferred. Rhatany, kino and tannin are chemically incompatible with gelatin. Lozenges made up with fruit paste also produce an immediate local effect, and this base can be used for most lozenges, those containing carbolic acid being exceptions. The hard base of the officinal lozenge and the compressed tablet form, therefore, are, generally speaking, suitable only when a constitutional action is aimed at together with a prolonged local effect, *e. g.* the morphia and ipecacuanha lozenges and the codeine lozenges. Bromide of potassium, chloride of ammonium, borax and chlorate of potash are largely prescribed as compressed tablets as cheaper and more convenient for carrying about than when a fruit base is employed.

Lozenges. — Trochisci Sedativi (containing $\frac{1}{10}$ gr. of extract of opium in each); Trochisci Cocainæ ($\frac{1}{10}$ gr. of cocaine); Trochisci Acidi Benzoin. Co. (containing hydrochloride of cocaine and codeine); Trochisci Morphinæ cum Ipecacuanha and Trochisci Orthoformi, all have an *analgesic* action.

Trochisci Boracis is merely *sedative*, and Trochisci Acidi Carbolici is antiseptic and stimulant as well as sedative in action. The following have a *stimulant* effect: Trochisci Acidi Benzoici, Trochisci Ammonii Chloridi, Trochisci Ammonii Chloridi Co. (containing also cubebs and chlorate of potash), Trochisci Cubebæ and Trochisci Potassii Chloratis.

For relaxed conditions the following *astringents* are largely used: Trochisci Krameriæ, Trochisci Krameriæ Co. (containing cocaine), Trochisci Catechu. Trochisci Acidi Tannici is rather too astringent for prolonged employment and liable to upset the digestion.

Trochisci Guaiaci is said to be antiphlogistic and is also given in rheumatic and gouty subjects.

A number of proprietary lozenges containing either menthol or formic aldehyde are largely consumed by the public; the former are sedative and stimulant and the latter antiseptic, and they appear to be often of much service.

The well-known Brompton Hospital Lozenge owes its sedative action to liquorice and anise seed, and the ordinary "delectable lozenge" to tolu. Marshmallow pastilles are merely demulcent; they serve to keep children quiet after tonsillectomy; there is often difficulty, however, in getting them fresh, and they are expensive.

Pastilles and lozenges cause less disturbance of appetite and of digestion when taken after food, but when an analgesic effect for the relief of dysphagia is aimed at they should be used a quarter of an hour before each meal.

In conclusion it is well to bear in mind that the most frequently prescribed lozenges, viz. the chlorate of potash and the tannic acid, are not suitable for prolonged use, and are perhaps best avoided in many patients: that nothing much can be expected from antiseptic lozenges which are necessarily weak and when dissolved in the saliva pass into the gullet without reaching the crypts and other regions harbouring pathogenic microbes: that they are most useful in sedative form for relieving cough and irritability and that even then such a valuable lozenge as that containing morphia and ipecacuanha probably owes its efficacy as much to its constitutional as to its local action. Even the astringent and the stimulating forms which are often most

effectual in subacute and chronic conditions may upset the appetite and digestion if taken too frequently and for long. Those containing cocaine or morphia must be given with special caution even although the dose is so small.

Pastilles.—The following pastilles (Throat Hosp. Phar.) are made up with a glyco-gelatin base—

Pastillus Bismuthi (sedative).
Pastillus Bismuthi et Morphinæ (sedative).
Pastillus Cocainæ ($\frac{1}{10}$ gr.) (sedative).
Pastillus Menthol ($\frac{1}{6}$ gr.) (sedative).
Pastillus Ammonii Chloridi (stimulant).

Powders for Insufflation

Powders are most conveniently applied by means of special insufflators, a straight nozzle being employed in the fauces and in the pharynx and an angular one for the naso-pharynx and for the deeper regions of the pharynx.

Analgesic. For the relief of painful dysphagia.—The following can be insufflated separately or together—

Chloretone gr. v–x
Anæsthesin gr. v–x
Orthoform gr. v–x.

The latter is useful in ulcerative conditions only.

℞ Morphinæ Hydrochloridi
Sacch. Lactis } (āā gr. $\frac{1}{4}$ ad $\frac{1}{2}$
Acaciæ Gummi gr. i.

In the painful dysphagia of tuberculosis of the laryngo-pharynx this sometimes gives relief for many hours.

Analgesic and Antiseptic.

℞ Orthoformi gr. v
Iodoformi gr. v
Menthol gr. ss.

In cancerous and other ulcers.

℞ Cocainæ Hydrochloridi gr. x
Morphinæ Hydrochloridi gr. iss
Menthol gr. x
Iodoformi ʒ ii
Acidi Borici ʒ ii.

Five grains at each insufflation in painful dysphagia.

Inhalations

Cold dry inhalations are not nearly so much used in inflammatory conditions in the pharynx as in the larynx. The same remark applies in a lesser degree to steam inhalations though they are sometimes found comforting in acute inflammations in the region of the fauces. For formulæ the reader is referred to the section on *Laryngeal Therapeutics*.

The Application of Heat and Cold

Heat.—The simpler methods of applying heat externally in the region below the angle of the jaw in acute tonsillitis and pharyngitis are so well known as scarcely to need enumeration, they include—

(1) The warmed comforter or small shawl.
(2) Cotton-wool or flannel, or spongiopiline, heated before a fire or in an oven, and kept in position with the hand or retained by a flannel bandage.
(3) Hot compresses and poultices.
(4) An india-rubber hot-water bottle or pillow.

Special apparatus include—

(5) Leiter's coil of leaden tubes with a continuous stream of hot water from a receptacle. The more modern rubber coil incorporated in a flat pad, and attached to a spirit-lamp apparatus, has the disadvantage of requiring skilled attention.
(6) The Thermos flask.
(7) The electric poultice, which has the advantage over the rubber hot-water pillow in that continuous heat can be obtained by connecting the apparatus with a wall-plug. By a special arrangement in the newest patterns the degree of heat required can be exactly regulated.

Internally, heat can be applied in the form of hot steam inhalations of benzoin, creolin or similar preparations. Hot mouth-washes appear to be of some use at times in acute inflammations of the fauces, especially in those cases where the drinking of hot tea and other drinks gives relief, but gargling is not usually well borne in acute disease.

Cold.—Although the sucking of ice is frequently advised for acute sore throat, it is to be doubted if it is often of any service for that purpose; on the other hand as a hæmostatic after operations it is frequently most valuable.

Leiter's continuous coil for the external application of cold was advocated as a routine measure in acute inflammations of the throat by Lennox Browne, but most practitioners rely on the hot coil rather than the cold, and the same applies to the ice-bag.

Cauterising Agents

The use of caustics either pure or in strong or in weak solutions was in former times almost a routine measure in most inflammatory lesions, whether acute, subacute or chronic, in the fauces and pharynx, whereas to-day many experienced specialists scarcely ever apply them; and on the exceptional occasions when they do have recourse to a destructive agent they usually rely on the electric cautery, which can be applied with greater surface precision than any solution, and any desired depth of

penetration can be effected. (See sections on *Pigments* and on *Electrical Methods*.)

Paquelin's cautery and the galvano-cautery snare is of service for the palliative removal of portions of malignant growths blocking the fauces and pharynx, and thereby interfering with deglutition, articulation and even respiration.

Electrical Methods

Faradism and Galvanism.—There is no wide scope for the employment of electrical currents in the fauces and pharynx. In paralysis of the constrictors of central origin electricity is not of much value. In obstinate *peripheral nerve paralysis* and paresis of the palate following diphtheria and influenza, faradism should be employed as long as there is any faradic reaction present; when the latter is lost galvanism can be applied either internally or externally. In *paretic palate* resulting from prolonged nasal catarrh the lesion is not a nerve one, but probably myopathic in some degree, and the application of the interrupted, *i. e.* faradic, current probably has an action of the nature of massage, and is not superior to vibratory massage. In *clonic spasms* of the palate and pharynx, faradic and galvanic currents are of doubtful service, but the sinusoidal current has been advocated in some quarters, as has also high frequency. In functional paresis of the fauces and pharynx with dysphagia, faradism sometimes works wonders, the element of suggestion no doubt having some share in the result in many cases.

Ionisation and Electrolysis.—These methods have rarely been used in the pharynx. Ionisation is too cumbrous a method to employ for the stimulation of indolent ulcers where caustic methods are equally useful; and though it has been claimed that electrolysis has occasionally been successful in bringing about the almost total disappearance of growths of moderate malignancy,. *e. g.* some endotheliomas and sarcomas, and Matthey of New York has attained some degree of success with zinc-mercury electrodes in carcinoma, yet the results are neither numerous enough nor striking enough to warrant recourse to them in inoperable cases of malignant disease in view of the fact of the more effective results of other methods, *e. g.* by radium and by surgical diathermy.

The Galvano-Cautery.—This is undoubtedly a convenient agent for producing destructive cauterisation when redundant tissue has to be removed, for producing fibrosis in tuberculous lesions, for the stimulation of indolent ulcers and for reduction of hyperæsthesia and paræsthesia by destroying temporarily the nerve-endings. The method is far less resorted to than formerly, when it was carried out as a routine measure though in a haphazard way in almost every case with chronic trouble in the throat. At the present day many experts rarely find occasion to employ this or any other method of cauterisation in the fauces and pharynx.

It is a very slow, frequently painful and often inefficient procedure for the reduction of enlarged tonsils. In what is known as granular pharyngitis, the projecting islands of hyperplastic lymphoid tissue are rarely the cause of the paræsthesia and other symptoms complained of, and these symptoms are rarely relieved by cauterising the so-called granules. The same may be said of prominent veins at the base of the tongue, though in this region the removal by the cautery point or with electric snare of redundant lymphoid tissue (lingual tonsil) in contact with an irritable epiglottis is sometimes useful in pharyngeal paræsthesia with cough. The cautery snare causes much more reaction than a pair of sharp scissors in uvulotomy. In angiomatous conditions and in small multiple papillomata the galvanic cautery is indicated when radium treatment is not available.

As regards the technique of its employment the same methods and precautions are necessary as in nasal electric cauterisation (*q. v.*).

Diathermy.—The production of aseptic necrosis in large inoperable tumours of the pharynx and exceptionally for the reduction of very large tonsils can be accomplished by the employment of a special form of high-frequency apparatus by which deep coagulation and cauterisation is effected. The reader is referred to the special article on this subject (*q. v.*).

Fulguration.—This form of high-frequency current is advocated by Dr. Keating Hart of Paris. The sparking is applied from five to ten minutes according as the malignant growth is of moderate size or of considerable dimensions. It does not, like the Diathermic and Desiccation methods, produce destruction of the growth, but is said to affect the nutrition of the tissues and render the soil less fertile for the proliferation of the cancer cells; whether cancer growth can effectually be inhibited and atrophied to the extent claimed by the originator of this comparatively simple method remains to be confirmed.

Desiccation by Static Electricity of High Tension.—By this method the spark used is not hot enough to carbonise the malignant tissues, but only sufficient to cause rapid dehydration, thereby rupturing the cell-capsules and converting the area treated into a dry mass. Clark of Philadelphia claims a wide application and a considerable measure of success for this procedure in the reduction of innocent and malignant growths in the nose, pharynx and elsewhere. He even employs it for the reduction of hypertrophies such as enlarged tonsils and adenoids. In cancerous growths

whilst accessible superficial lesions can be desiccated the glands and deeper extensions are best dealt with either by the X-rays or with radium.

Whether these claims on behalf of desiccative methods will be substantiated by others remains to be seen.

The X-Rays

Since the introduction of treatment by radium the older method of Roentgen radiotherapy has not been much used in the fauces and pharynx; and when employed the application is usually made from the outside towards the angle of the jaw and side of the neck for large *malignant growths* of the fauces and base of the tongue, for invasions from the larynx, for cancers of the deep pharynx, and more especially for the glandular extensions in the neck. It has also been applied through the mouth, in America, for growths in the region of the faucial ring.

Quite recently Steuart of Birmingham has claimed some measure of success from the use of X-rays in the partial *reduction of enlarged tonsils* and also adenoids in cases where operation is either undesirable or undesired. It is too soon to say whether the method is worth the trouble involved in its employment and is of any use in indurated large tonsils of long standing. The following is Steuart's summary of the technique: "A hard tube having a penetration of nine Wehnelt units was used, the rays were filtered and not more than a half Sabouraud dose was allowed to pass through any given area of skin. The rays were applied laterally, the anticathode of the tube being above and behind the angle of the jaw, so that the rays encountered the minimum resistance in reaching the tonsil; the head was so placed that the rays swept in front of the vertebral column and the posterior pharyngeal wall. After a dose had been given on one side the head was turned and a similar treatment given on the other side.

"All measurement was done with a pastille lying on the skin. With restless children it is useless to adopt Sabouraud's plan of having the pastille half-way between the anticathode and the irradiated area.

"The tube was placed at a greater distance from the patient than is usual in order to obtain approximate equality of intensity of radiation throughout the pharynx.

"The interval between the doses was usually three weeks, but under no circumstances was a larger dose than a half Sabouraud given."

Screened Radium Salts and Radium Emanation

The mode of action, possibilities and limitations of the radio-active rays of radium in innocent and malignant tumours in general, is dealt with in a separate article in this work. The method is now extensively employed in cancerous disease in the faucial region, the pharynx, the larynx and the gullet. The remedy is a very uncertain one, but very substantial palliative results, sometimes amounting to temporary disappearance of naked eye evidence of disease, have been recorded in an encouraging number of instances where, though operation was either contra-indicated or rejected, yet the growth was not too advanced. It is very occasionally useful in so reducing a cancerous condition considered inoperable as to permit of subsequent surgical removal with success. As a rule, however, the cases one is asked to deal with are not only inoperable, but so far advanced

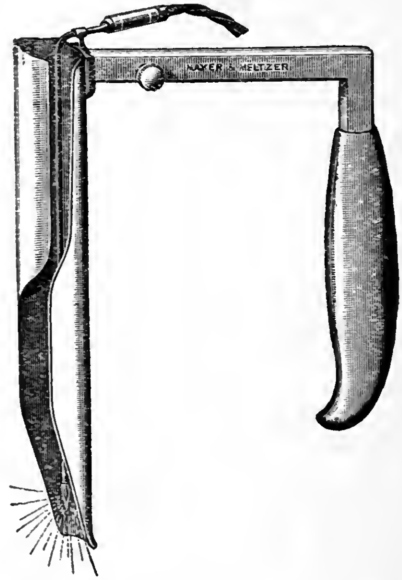

Fig. 5.—Hill's direct Pharyngoscope and Laryngoscope, with distal lamp, for inserting the radium apparatus in pharyngo-laryngeal malignant diseases.

as to be untreatable, so that little can be hoped for beyond such a reduction of the growth as will palliate the more distressing symptoms, such as mechanical difficulties to swallowing and respiration, painful ulceration and excessive secretion. So-called recurrences, that is, small areas of growth which make their appearance early after an unavoidably imperfect removal by operation, are always worth dealing with by radium therapy, and gratifying palliative results and even temporary apparent local cures are occasionally obtained. Of malignant growths, endotheliomas and other forms of sarcomas react in the throat (as in the gullet and elsewhere) more readily to radium rays than do true carcinomas; squamous epitheliomas seem to be least favourably influenced of any, but I have seen at least six such cases, four

being in the deep or post-cricoidal pharynx, which have reacted quickly and very markedly to repeated applications of radium, with consequent

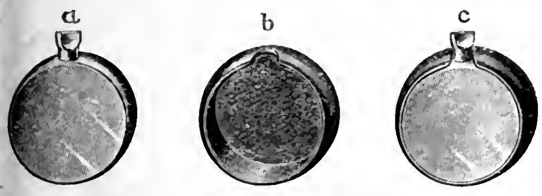

FIG. 6.—Circular box which, when charged with emanation, is sealed at *a*; *b* is an extra screen to protect healthy tissues, which fits on *a* as in *c*.

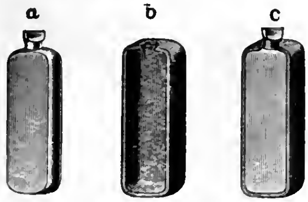

FIG. 7.—*a* is a metal box for radium emanation, with walls 1 to 2 mm. thick; *b* is an additional screen to fit over *a* as in *c*. to protect the adjacent healthy mucosa. This form of apparatus is employed in post-cricoid cancer.

symptomatic relief for periods varying from six to eighteen months. In these cases the glandular and other extensions led to the fatal issue rather than the primary throat lesion. There are some recorded instances of sarcoma limited to the tonsil having apparently disappeared altogether. A small tube should be inserted into the growth and an emanation box applied to the faucial surface. Such cases, however, are more quickly and certainly dealt with by operation, radium therapy generally speaking being reserved for those in which operation is either contra-indicated or declined. Radiation can, however, be usefully employed after operation.

In my own practice I have usually employed one or more tubes containing 100 mg. of radium bromide (or its equivalent in other salts of radium) or tubes or caskets containing the emanation equivalent.

The drawback to the use of emanation is that it loses its radio-activity, the fall being rather rapid to begin with, so it is reduced to half strength in something under four days. As the curve is, however, definitely known, one is able to order approximately a dose equivalent to say 100 mg. of radium bromide for a twelve-hour application, the radio-activity being higher than that amount to begin with, but averaging out fairly correctly. On the other hand, against this disadvantage compared with the use of tubes of pure radium salts, where there is only a negligible variation in strength, it is at times a great convenience to be able to get a box or casket built to a size and shape suitable for each individual case, and the emanation is then equally distributed throughout the containing chamber, whereas with tubes only partially filled with radium, as many are, the distribution of the radium salt in the tube is affected by position.

In my own practice I have almost entirely worked in the throat and gullet in conjunction with Finzi, using his radium tubes enclosed in platinum screens; which latter have the advantage of being more efficient than either lead, silver or German silver of the same degree of thickness; this thickness in Finzi's screens varying from $1\frac{1}{2}$ to $2\frac{1}{2}$ mm. It is alleged that there is a drawback to platinum as a screening agent in that it gives off a more powerful secondary radiation than either lead, silver or German silver, but as all screens are enclosed in rubber to counteract this secondary effect it is probable that the objection to the use of platinum is more theoretical than practical.

In using tubular screens an outer screen with a window on one side is useful in the deep pharynx and in the gullet when the lesion has not yet become annular, but is limited to a

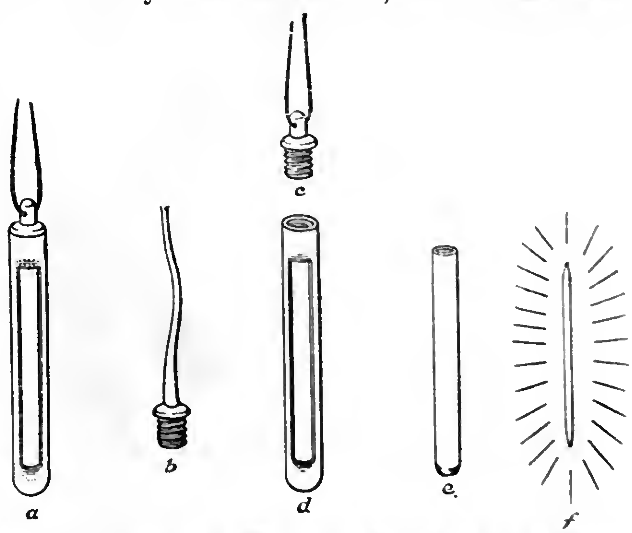

FIG. 8.—*f* = capillary glass tube containing radium emanation which is enclosed in the metal tube *e*, whose walls are 1 mm. thick; this again can be enclosed in an additional screen, *d*, with a window which is arranged adjacent to the growth; the whole is secured by a screw cap, *c*, which has a string through it; or a cap *b* with a long flexible silver style attached can be substituted more especially for œsophageal cancer.

certain part of the wall, *e. g.* to the back of the cricoid plate or to the pyriform fossa; the thinner part of the screen, *i. e.* the region of the window, is then accurately placed against the

cancerous area under direct vision through the endoscope and the non-invaded areas are protected by the additional thickness of metal; and further protection can be obtained by interposing an additional layer of rubber or lint. In the fauces and mesopharynx a roll of lint tied on to the surface of the tube which is away from the growth forms quite an efficient screen by distance for the protection, for example, of the healthy uvula and palate or for the epiglottis. Where an emanation box is employed an accurately fitting cap of lead or other metal can be used as an additional screen to protect healthy parts over and above the 2 mm. thickness of the box, which is only separated from the surface to be treated by rubber 1 mm. thick.

Having fitted up a suitable apparatus for any special case, either one tube, or two tubes abreast, or an emanation box of suitable size and shape with correct screening arrangements, the next thing to be considered is how to retain it accurately in contact with a desired area. In the case of the deep pharynx this is quite simple, as the radium apparatus is tied on to the middle third of a small œsophageal bougie, one end of which is passed into the gullet to anchor, so to speak, the whole apparatus below, and the proximal end is clamped to the teeth or to a denture. In the region of the fauces and lateral wall of the mesopharynx the ordinary gum elastic bougie is unsuitable for retaining the radium tubes or an emanation box in accurate contact with a diseased area, but I have had no difficulty since I adopted the plan of tying the radium apparatus to my styletted œsophageal tube (see p. 280), which is much more comfortable than tonsil pressure forceps. My apparatus consists of a red rubber tube 5 mm. in diameter, through the lumen of which passes a flexible silver style attached to a vulcanite terminal. This tube can be moulded to any required curves or angles after the distal extremity has been anchored in the œsophagus, and the attached radium apparatus can thus be accurately approximated to the growth in any desired position. This arrangement can often be retained *in situ* for twelve hours on a stretch, the patient being under morphia and atropine; but if there is much cough and irritation, or much septic secretion, it is better to be content with a six hours' application repeated at an interval of a day, or two or three applications of four hours each. These time-doses apply also to the pharynx, when 100 mg. of radium bromide or the emanation equivalent is employed with a 2 or $2\frac{1}{2}$ mm. metal screen encased in rubber in contact with the growth. It is best to apply two or three tubes arranged abreast for larger growths, rather than make two or three applications of twelve hours each on different areas. A word of caution is necessary in reference to cancers involving the laryngo-pharyngeal margin, *e. g.* the ary-epiglottidean folds and arytenoids; here the pressure of the apparatus alone may cause greatly increased tumefaction in the course of three or four hours leading to respiratory obstruction and retention of secretion. Moreover, as swallowing during the application is not always efficient, septic secretion may pass into and infect the air passages, when a large cancerous mass is complicated by a good deal of foul discharge. Moreover, in some cases the presence of the apparatus induces a good deal of salivation unless this is kept under control by morphia and atropine injections. I know of one case in which laryngeal stenosis necessitating tracheotomy followed the employment of radium for pharyngo-laryngeal carcinoma, and in a case in which I made the application myself for such a lesion, the patient died a few days later from septic pneumonia, which I strongly suspect was due to septic discharges passing into the air passages instead of being swallowed. In post-cricoidal carcinoma there is no passage left for swallowing when the apparatus is in position, and expectoration has to be relied on to get rid of excessive secretion, but it is only in lesions extending to the laryngeal vestibule that I have known serious complications occur. In treating the fauces the patient can swallow saliva fairly easily provided a small styletted tube is employed so that there is little danger of either laryngeal stenosis or the inhalation of septic discharges. In some intolerant patients and in those without sufficient fortitude, the apparatus has to be placed in position under general anæsthesia in deep pharyngeal cancers, but in my practice an injection of morphia and scopolamine, together with the local application of cocaine applied by the brush, has in the majority of cases been sufficient. When the disease is in the region of the lateral walls or laryngeal orifice, *i. e.* low down in the mesopharynx, and also when in the deep pharynx, the apparatus is best inserted through a large-sized open direct pharyngoscope (see p. 266). Great care must be taken to ensure that the apparatus is in its correct position, and the flexible silver wire of the tube must be forthwith bent in such a way as efficiently to retain it there. Frequent inspections, if necessary with the throat mirror, are of course advisable in cases where there is any tendency to coughing or vomiting, which might slightly shift the apparatus. Some patients suffer a good deal from thirst when much morphia and atropine has to be administered, and sucking ice often makes them more comfortable.

It is permissible in the case of very large growths to make two or three incisions into the tumour and bury two or three tubes in it. In

a patient under my care two years ago, no less than four tubes were inserted into a large naso-pharyngeal sarcoma which filled the naso-pharynx and pushed the soft palate forwards within an inch of the teeth. Before treatment he swallowed with difficulty, could only breathe through a tracheotomy tube, and was extremely deaf. A tube was inserted into the growth through each nostril, and two others through the mouth. At the end of a fortnight the naso-pharynx was comparatively clear, he could hear perfectly with one ear, and fairly well with the other, swallowing was normal, and the tracheotomy tube was dispensed with. Further treatment of the bone invasion was disappointing.

As cases referred for radium treatment are usually advanced and inoperable, the glands in the vicinity are frequently involved, and these must be treated either immediately after or before the primary lesion. The technique is necessarily different where healthy skin and subcutaneous tissues intervene, and this matter is fully dealt with in the special section on Radium Therapy (*q. v.*).

If the growth gives an unequivocal response to the treatment this will usually be evident in from one to three or four weeks, and the question of repeating the dose will then arise. Finzi follows the practice of Dominici of waiting till the reaction is well over, and not making a second application till about six weeks after the first. This course is also adopted at the Radium Institute, and the method, formerly so general in France, of giving large weight-doses and small time-doses frequently repeated with short intervals is not usually adopted in this country to-day, though it should be mentioned that Guisez's rather successful early observations with radium in cancer of the pharynx and gullet were carried out by the older and more tedious method.

To suggest the employment of radium for the removal of *innocent new growths* may seem on a par with breaking a fly on a wheel, but there are two conditions of the pharynx—of great rarity, it is true—in which radium treatment is likely to be more convenient and efficient than any other, viz. in extensive spreading lesions of an angiomatous character, and in recurrent multiple papillomata. Radium rays usually act well in contracting vascular growths in any region, and it has been shown by Abbé that it is equally efficacious in dealing with multiple papillomata of the larynx which tend to recur after repeated operation. Exceptionally, the condition spreads from the larynx to the pharynx and gullet, resisting all treatment, and Robinson has recorded a death in a case in which this extension took place. It would be worth while to give radium treatment a trial in such a case. Abbé employs only short exposures of half an hour, which can be repeated, and he uses a thin screen only.

Therapeutic Inoculation

Seeing that the throat is so commonly affected by septic inflammations, by diphtheria and by tuberculosis, it follows that treatment by serums, vaccines and antitoxins is of very wide and frequent application in this region. The subject, however, is fully discussed under the special section devoted to these methods generally, which renders it unnecessary to go over the same ground again; but attention may be called to the recently introduced practice of *local serum-therapy* more especially in diphtheritic lesions in the throat. A special serum which is possessed both of antitoxic and bactericidal properties is applied locally to the patches as an adjunct to the usual routine injection of diphtheria antitoxin. Such a serum is obtained by injecting an already immunised horse with living diphtheria bacilli. Horse serum already rendered antitoxic then contains antibodies which neutralise and destroy the bacillus itself. Behring long since insisted on the value of local applications to the lesions and does so again in his latest work. Leroy, referring to this adjuvant treatment, states that several months' experience in his diphtheria wards had convinced him that local applications of serum modifies the course of the attack. It has also been recommended as a prophylactic in scarlatinal and other lesions of the throat which tend to be complicated by diphtheria more especially during epidemics. It has likewise been employed with a view to sterilising the mouth and throat of "carriers." Whether the claims for this topical method made by Leroy, Dutour and others is destined to be unequivocally established in diphtheria and in other microbic diseases in the throat remains to be seen. The modern practice here in diphtheria at all events has been in the direction of avoiding local applications in order to disturb as little as possible patients who are so liable to fatal heart failure. W. H.

THE TREATMENT OF THE COMMONER DISEASES OF THE FAUCES AND PHARYNX

Acute Tonsillitis and Pharyngitis.—The acutely inflamed tonsil may be very enlarged (*Parenchymatous Tonsillitis*)—or the outstanding feature may be the presence of scattered croupous exudation from the mouths of the crypts, with or without marked enlargement (*Lacunar*, otherwise called *follicular* or *Discrete Exudative Tonsillitis*)—or the tonsillar surface may present a large patch of false membrane which is usually due to the Klebs-Lœffler

bacillus (*True Diphtheritic Tonsillitis*)—or membranous tonsillitis may exceptionally be due to the presence of some coccus or bacillus, *e. g.* pneumococcus, or of Vincent's organisms (*Pseudo-Diphtheritic Tonsillitis*). The first two and the fourth of these varieties of tonsillitis are not specific, but are probably always associated with microbic infection, often of a multiple character, and are usually more or less contagious. Tonsillitis forms one of the multiple lesions of scarlatina and of measles. It is also antecedent to every quinsy.

The tendency in former times was to concentrate effort on the local rather than on the general constitutional treatment. To-day strong antiseptic pigments are considered worse than useless because not only do they not reach the septic crypts, but they increase the pain. This is generally correct, but in the very early stage of cases of recurrent tonsillitis it is sometimes useful to apply pure guaiacol, after previous cocainisation, to the surface of each tonsil to try and abort the attack, a not unusual sequence when the lesion is still superficial. Gargling is painful and probably useless, even if the patient makes a conscientious effort to carry it out. Warm mouth-washes of listerine or glycothymoline tend to cleanse the mouth and the teeth and are always soothing. Atomised cocaine is disappointing in small doses, and may affect the heart and cause insomnia in large ones, and it causes a feeling of increased tumefaction. Alkaline sprays are useful when there is much ropy mucus clogging the fauces; nothing is better than nebula alkalina applied by means of a De Vilbiss coarse atomiser with an adjustable nozzle. An atomised solution of permanganate of potash is useful when there is much fœtor and sepsis. Demulcent and anodyne pastilles sometimes do good; antiseptic lozenges are probably useless, and when they do appear to relieve—as, for instance, the carbolic acid lozenge—the effect is due to the analgesic rather than to the antiseptic action of the drug. Chloretone, orthoform and morphia insufflations are not so useful in very painful cases of tonsillitis as they are in throat conditions where the surface is broken and ulcerated. External hot applications are always comforting, however applied; Leiter's continuous cold coil was once almost a routine measure in the practice of some throat specialists, but hot water is now substituted for the cold. Relief of pain during the taking of fluids is sometimes afforded by some one standing behind the patient and making firm pressure with the hands on the ears and side of the jaws during the act of deglutition.

Although the general treatment is so much more satisfactory than any local symptomatic treatment, yet it can be summed up in a few words, viz. an initial purge of calomel followed by a saline, the frequent administration of aspirin or allied drugs, and a cautious resort to a hypodermic injection of morphia and atropine to procure sleep and relief from excessive pain. Therapeutic inoculation should be resorted to where the disease is due to a specific organism, *e. g.* antitoxin in diphtheria, or a stock serum, followed by an autogenous vaccine in severe or recurrent cases where micro-organisms such as the streptococcus, the micro-coccus catarrhalis, the pneumococcus, Friedlander's bacillus, or the influenza organism are found to predominate. Where Vincent's organisms are present the result of vaccine therapy has been rather disappointing in my hands; the application of powdered salvarsan is now employed to kill the spirochœtes. If the exudation is long continued the disease is best got rid of by complete excision when the inflammation becomes subacute. If cases hang fire during the *subacute stage*, especially if there have been previous attacks, the question of complete excision should arise, and in recurrent cases this is clearly indicated during the quiescent period. The rheumatic factor in some cases must be borne in mind.

During convalescence, especially in anæmic subjects, iron preparations may be needed. Each convalescent, however, will require treatment according to the special indications of the case; but as relapses are not uncommon, and as the state of debility often leads to the recurrence of other dormant troubles, it is well to bear in mind that to continue treatment during the stage of recovery, and after, is not the least important function of the practitioner in dealing with a case of severe tonsillitis.

Quinsy (Palatine or Peritonsillar Abscess) is the popular name for an acute tonsillitis *plus* a peritonsillar or epitonsillar (palatal) abscess. An acute true intra-tonsillar abscess is extremely rare, the writer having only met with two unequivocal cases; the reason is to be found in the structure of the gland, which is riddled with crypts or lacunæ, whereby the discharge of inflammatory products out of the mouths of the lacunæ is facilitated. In cases of acute tonsillitis, however, an extra-tonsillar abscess often forms in the palate above the superior pole of the tonsil, and sometimes externally and posteriorly between the planes of the pharyngeal portion of the deep cervical fascia. Acute tonsillitis with a super-added adjacent peritonsillar abscess constitutes a quinsy. Infection is supposed to penetrate the capsule into the epitonsillar (palatal) cellular tissues from the *crypta magna* or "tonsillar recess," which opens into the supratonsillar fossa. Some authors consider that an abscess may occasionally form in the "recess" itself by

the blocking of its mouth by parenchymatous swelling accompanying acute tonsillitis.

The patient is unable to drink, eat, expectorate or cough without pain, and, as sleepless nights are super-added, complete mental and physical prostration soon results in severe cases. These symptoms rapidly disappear in most cases after evacuating the pus by an incision through the anterior pillar or through the most prominent part of the bulging palate. Incising the tonsil itself is useless, and endeavouring to evacuate the abscess by means of an angular metal searcher or director inserted into the tonsillar recess is extremely painful and unsatisfactory from the point of view of hitting off the abscess cavity, and of subsequent drainage. Tonsillectomy has been recommended, but not often practised. The pus having been found by a palatal incision, sinus forceps are inserted and opened and the abscess evacuated by pressure; this can be followed by injection of hydrogen peroxide. Should prompt incision be refused, heat externally and mouth-washes may possibly hasten the bursting of the abscess, as subsidence rarely happens; spontaneous evacuation takes place either between the glosso-palatine fold and the superior pole of the tonsil, through or in the region of the tonsillar recess, or through the palate, and very exceptionally behind the pharyngo-palatine fold. When the last happens, the case has probably been complicated by a lateral pharyngeal abscess; the latter condition may, in fact, have been the prominent feature throughout. There is said to be a danger from septic pneumonia when abscesses burst during sleep from inhalation of pus. After the evacuation of the palatine abscess the symptoms may only be partially relieved, and there may be an apparent relapse. In these circumstances search should be made for a *lateral pharyngeal abscess* behind the pharyngo-palatine fold; this complication is rare, but, if found, should be opened from the pharynx by means of a pair of angular scissors or an angular bistoury; an external cervical operation is rarely necessary. Exceptionally a second abscess may form above the opposite tonsil at an interval of some days from the appearance of the first. General *septic phlegmonous or œdematous inflammation of the pharynx*, often extending to the larynx, a highly dangerous condition, may be mistaken for a quinsy; it is rarely, if ever, a complication of a true quinsy, and is more probably always a distinct disease *ab initio*, being characterised by a tendency to spreading œdema, rather than to the formation of a localised abscess. A quinsy is, of course, in the first instance a localised phlegmon, and it is a moot question whether incision is advisable before there is evident pus formation. Although most authorities advocate incision when there is evidence of abscess, it is fair to state that Harmer is opposed to surgical interference, and holds that patients suffer less if the abscess is allowed to take its course and either burst or subside.

After complete recovery the question of excision of the tonsils should be considered in cases of a recurrent quinsy, as the cause of this is usually to be found in a septic condition of the crypts (chronic lacunar tonsillitis). As the glands in the neck are frequently inflamed in quinsy, the danger of chronic cervical adenitis as a sequela should be urged when the patient is inclined to refuse early palatine incision.

Enlarged Tonsils—Simple Enlargement of the Tonsils without Lacunar Deposits—Chronic Inflammatory Enlargement of the Tonsils.—Children with considerably enlarged tonsils often enjoy good health, and if the tonsils are only moderately enlarged, give rise to no symptoms and are free from septic matter in the crypts, there seems no urgent reason for surgical interference; should, however, deafness, mouth breathing and other symptoms be present, and should there be enlarged glands in the neck or a history of recurrent attacks of acute tonsillitis, or of peritonsillar abscess (quinsy), then excision and the completer the better, is indicated, together with the removal of adenoids, if present. Whillis' guillotine method is now largely adopted in this country and America. This can be carried out by any rigid guillotine, but there is an advantage in using Elphick's modification of Ballinger's instrument, as it has two blades, one for crushing and enucleating the tonsil entire in its capsule, and another sharp one for severing it from the crushed stump.

The important question of latent tubercle bacilli in the crypts of enlarged tonsils has brought forth most contradictory opinions. Whereas Levy and Chiari found that in 1085 patients actually suffering from laryngeal tuberculosis there was clinical evidence of tuberculosis in less than two per cent.; on the other hand, Wood gives 69 per cent. of tuberculosis cases examined as suffering from tonsillar tuberculosis. The discrepancy is probably to be explained by the want of distinction between clinical and latent tuberculosis of the tonsils. Still, considering that the tonsils are amongst the acknowledged avenues of entry of tubercle bacilli into the system, Wood's statistics are sufficiently disquieting, and many for this reason prefer to advise removal of enlarged tonsils unless there are special *contra-indications*, *e. g.* in hæmophilic subjects, and in cases of anæmia, status lymphaticus, leukæmia, cardiac disease, epilepsy, or extreme debility where an operation might be dangerous from shock, or other reasons.

In the latter circumstances especially, various

alternative measures to operation have been advocated from time to time; they are none of them to be depended on in large and hard tonsils of long standing, but are sometimes of some use in soft enlargements, more especially in recent cases following an acute attack of tonsillitis. Climatic treatment includes residence at places like Margate and Broadstairs, or a sea voyage. Preparations of iron, arsenic, iodine and phosphorus, singly or in combination, are largely used in recent cases; the iodide of iron, and such preparations as Parrish's Food, the syrup of the hypophosphites, malt extract, and cod-liver oil, appear to effect a real reduction in some instances in children. A measure of success has been claimed for lymphatic gland extract.

The employment of pigments containing either iodine, tannin, iron, creasote, carbolic acid and silver, while not such a routine measure as formerly, is still frequently carried out; personally I have abandoned the use of paints in simple enlargement of the tonsils, that is without septic crypts, and I regard any improvement observed under this treatment as rather in spite of the painting than because of it.

The employment of X-rays has recently been advocated by Steuart, for the reduction of soft, enlarged tonsils remaining over from an acute inflammation, and in cases where operation is contra-indicated. It is also claimed that the accompanying hyperplasia of Luschka's tonsil (adenoid growths) also undergoes a substantial reduction in many cases. Whether the method is likely to prove to be worth, even as a palliative measure, the trouble and the expense involved in several sittings it is as yet too soon to say. The technique is described under the heading of special therapeutics of the fauces and pharynx. Radium treatment might be expected to do all that is claimed for the X-rays, but the method by long exposures with a special apparatus would be impracticable in children quite apart from the question of expense and availability.

Chronic Lacunar Tonsillitis.—In this condition there are septic deposits in the lacunæ which keep up pharyngitis with one or more of the following, viz. sore throat, aching throat, a recurrent pricking sensation in the fauces, the feeling of a foreign body being present and both objective and subjective fœtor.

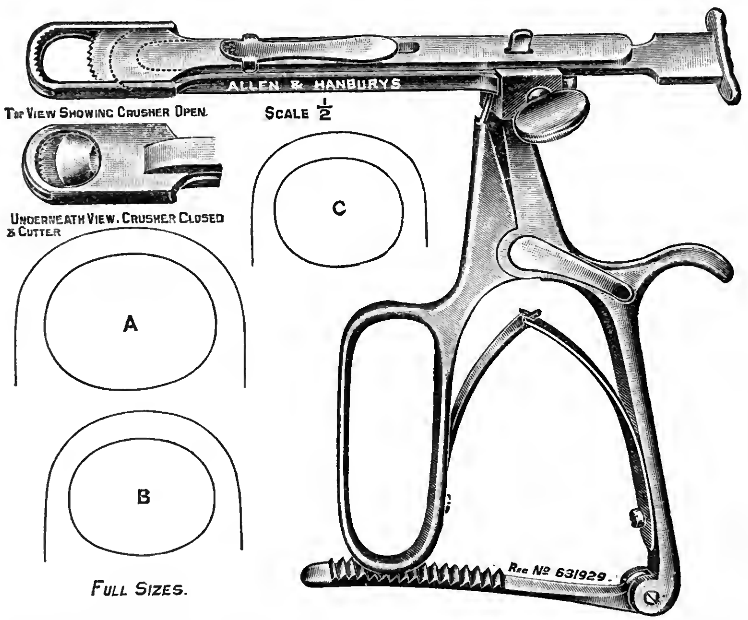

Fig. 9.—Elphick's enucleating guillotine with two blades, one for first enucleating the tonsil from its bed, crushing the stump, and the other a sharp one for severing the tonsil.

A genuine chronic lacunar abscess forms in some instances recurring at regular or irregular intervals and ending by the extrusion of a foul caseous core. The tonsils may or may not be markedly enlarged. The local and general treatment, without resorting to surgical interference, includes that already detailed under the heading of simple enlargements of the tonsils; but more attention is usually paid to local applications such as painting with either guaiacol, resorcin, glycerine of carbolic acid, iodine or menthol. It is, however, doubtful if these remedies ever reach much beyond the mouths of the crypts and they cannot penetrate to the depths of these recesses—when the disease is of long standing and general constitutional treatment together with change of air has been given a fair trial, there is only one satisfactory method of treatment and that is *complete* surgical removal of the tonsils, a dissection being necessary when the tonsils are buried in adherent pillars. Operation should never be delayed when the cervical glands are enlarged. If a cutting operation is contra-indicated galvano-cautery puncture carried out at several sittings may be tried. Dealing with isolated crypts in this manner or by slitting up is not recommended when there is no real objection to complete excision either by the guillotine or snare or dissection. As has been before stated, it is the septic state of the crypts rather than the size of the tonsils

which should be the guide in recommending complete removal.

Tonsillar Hæmorrhage. — Considerable bleeding immediately following tonsillectomy with short anæsthesia, which does not cease spontaneously after a few deep breaths, usually does so after syringing with ice-cold water; if this fails hot water syringing should be tried. General parenchymatous bleeding is best dealt with in the first instance by pressure, a pad of cotton-wool or lint dipped in hydrogen peroxide or adrenalin solution or in a paste of equal parts of tannic and gallic acid being pressed with the end of a pair of long forceps against the bleeding area for ten or even twenty minutes. Watson Williams' special forceps with one blade against the tonsil and the other outside near the angle of the jaw, is especially handy for this purpose. Pressure with the finger instead of the forceps is tiring but very efficacious. Applications of iron should be avoided, as they usually fail and a dirty sloughing surface results. Styptic collodion was at one time much recommended, but it is painful and rarely efficient, and gives rise to a

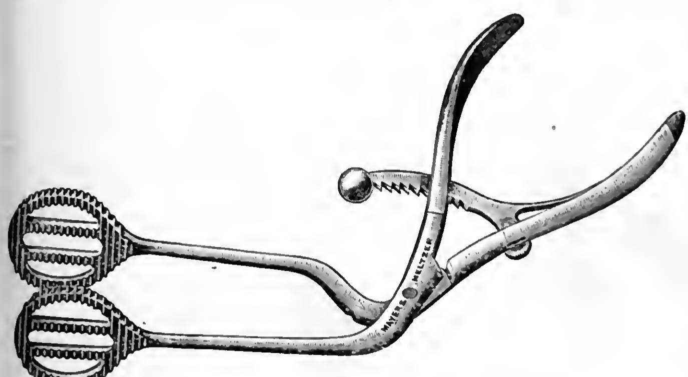

Fig. 12.—Watson Williams' Tonsil Forceps.

great deal of irritation and cough if any of it touches the epiglottis.

A spurting vessel can be clamped with a long pair of artery forceps and ligatured later if necessary. A special forceps with broad vertical blades for temporarily clamping the two pillars together is so useful and efficacious that it ought always to be at hand. If on removal of this forceps after half an hour bleeding begins again, it will save further loss of time to sew up the two pillars over a roll of lint dipped in styptic. This can be accomplished either by a long curved needle, or by a cleft palate needle, or more easily still by using Michel's hooks.

The instrument for closing the hooks and removing them the next day are here illustrated. If each hook has a silk ligature attached to it,

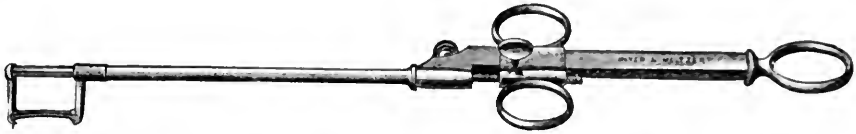

Fig. 10.—Instrument for suturing pillars of fauces with Michel's hooks.

Fig. 11.—Forceps for opening and removing Michel's hooks.

and the end secured outside the mouth, there will be no danger of trouble if the hook eats through. The drawback to applying Michel's hooks is that septic œdema of the fauces and palate is apt to supervene, and the same may follow the prolonged application of forceps and, in a lesser degree, sewing up with the needle; these three measures, therefore, should only be resorted to when simpler means fail, and they should be discontinued as early as possible.

The writer has on two occasions brought about the immediate cessation of serious and long-continued bilateral tonsillar hæmorrhage by pressure on the carotid arteries with the patient lying on his back on the floor. As fainting occurred on each occasion the pressure may possibly have been exerted on the vagi as well, and it is impossible to escape the reflection that such pressure might not be altogether free from danger.

The placing of a temporary, or of a permanent, ligature on one external carotid has been resorted to on a few occasions, but can rarely be called for if instruments for dealing with the bleeding area are at hand.

The value or otherwise of calcium lactate, whether before operation or after bleeding has supervened, is a matter on which there is much difference of opinion. The internal administration of drugs for which a hæmostatic action is claimed, such as gallic, sclerotic and sulphuric acids, iron, tannin, ergot, ergotin,

opium, stypticin, is a method too slow and unreliable in action to be worth considering except in moderate prolonged oozing. In the latter circumstance there is no harm in injecting either morphia or ergotin hypodermically. Inhaling amyl nitrite occasionally seems to do good and can be used in addition to local measures. Subcutaneous or rectal saline injections, or even transfusion, may be necessary where much blood has already been lost.

Malignant Diseases of the Tonsils and Fauces.—The local treatment varies at different stages of malignant growths, but is more or less identical whether the disease be carcinoma, sarcoma or lymphadenoma. In early stages when limited to the tonsil, *i. e.* when it has not permeated the capsule, excision has been successfully performed from the mouth with or without slitting the cheek. When, however, the glands at the angle of the jaw are enlarged and the folds slightly attacked, nothing short of Vohsen's operation is likely to succeed. An incision is made from the mastoid tip to the hyoid and then carried upwards over the angle of the jaw; the lingual, facial and ascending pharyngeal arteries are ligatured, and the jaw divided in front of the masseter and the ascending ramus pulled strongly forwards out of the way; this gives good access to the tonsillar bed; enlarged glands may have to be dealt with by additional incisions. When the disease demands a much more extensive operation than this, the chances of successful radical removal are immensely reduced. When the growth nearly closes up the fauces so as to interfere with swallowing, articulation and respiration, partial removal with the knife, galvano-cautery or surgical diathermy is justifiable and may give much temporary relief. Serious recurrent hæmorrhage may follow the placing of a temporary or of a permanent ligature on the carotid. Those requiring first-hand information should refer to the articles in *Burghard's System of Operative Surgery* by Waring and Trotter.

Non-operative palliative measures include the use of the X-rays and the employment of screened radium salts, either applied to the surface for a period which will not cause ulceration, or embedded in the tonsil so as to attempt to bring about aseptic necrosis. The glands should also be treated. Radium is a most uncertain remedy, but apparent temporary disappearance of the growth has now been recorded in a number of cases, and in other instances there is marked reduction in the size of the growth and in the symptoms. Sarcomas, more especially endothelial sarcomas, appear to respond better than epitheliomas. Electrolysis is said to have been beneficial in a few cases of sarcoma of only moderate malignancy. When there is great narrowing of the fauces on account of the large size of the growth, much palliative success has been attained in producing aseptic necrosis of the bulk of the growth by the new method of diathermy, which produces a wound which heals well. This is in marked contrast to radium when used to the extent of cauterisation, after which there is often no tendency to healing and there may be increased pain. Injections of Coley's fluid and of colloidal preparations of copper and of selenium have done substantial good in a few cases only. The other palliative measures, local and general anodyne, are identical with those employed in superficial cancers in other parts of the body. (See also section on *Special Therapeutics of Fauces and Pharynx.*)

Malignant Disease of the Deep or Post-cricoidal Pharynx.—Cancer in this region, if diagnosed in the early stages, can be dealt with by excision of a part of the pharynx by lateral pharyngotomy if the growth is limited to the posterior wall. When the back of the cricoid plate or the pyriform fossæ are invaded the larynx must be removed as well. The treatment of inoperable cases by radium has already been discussed. The same palliative measures as those described under the heading of Cancer of the Tonsils and Fauces apply here.

Acute Septic Pharyngitis.—The milder forms of this condition have already been alluded to as occurring in conjunction with acute tonsillitis; these include: (1) the superficial catarrhal form, and (2) the ulcerative and membranous forms due to a streptococci, staphylococci, pneumococci, Friedlander's bacilli, micrococci and Vincent's organisms. The lesions may much resemble those found in true diphtheria and in scarlatinal diphtheria. Three more varieties which are especially malignant are occasionally met with, viz. (3) the spreading œdematous form with cellulitis which tends to spread to the larynx and tissues of the neck, but not leading to suppuration, (4) the phlegmonous or suppurating form of cellulitis, and (5) the gangrenous form. The last three grave forms are often grouped together on the ground that any of the various infective organisms above-mentioned either separately, or in conjunction, may give rise to any one or in succession to all three of these pathological lesions, viz. cellulitis, suppuration and gangrene according to the virulence of the infecting agent or agents. The general treatment differs little from that of acute blood-poisoning elsewhere, and the same possible complications have to be combated as regards pneumonia, pericarditis, endocarditis, nephritis, etc. The high fever, if present, must be reduced by appropriate remedies; the poisoned

circulation must be dealt with in the first instance by the administration of an anti-streptococcal serum or of a polyvalent serum to be followed by an autogenous vaccine; and the strength must be maintained by a supporting diet of beef tea, raw eggs and milk together with stimulants. An initial dose of calomel and the administration of a mixture containing iron and quinine is the recognised routine as regards drug treatment. Oxygen should always be at hand for inhalation.

The local treatment necessarily varies with the course of the case. Extension to the larynx may demand incision of the œdematous tissues of the vestibule, and this is probably to be preferred to tracheotomy—in itself an exhausting complication: multiple incisions, after applying cocaine and adrenalin to the œdematous laryngeal tissues, has given instant relief in several cases under my care, and since adopting this method I have not had recourse to tracheotomy, but it may be necessary when the œdema spreads to the trachea. The same procedure is sometimes called for in the fauces and pharynx. The formation of abscesses should be watched and dealt with either by external or internal incision. In addition to these necessary local measures some practitioners worry the patient by local applications, but they probably do more harm than good. A sedative spray or inhalation may be soothing and hot fomentations externally are worth trying. If there is great difficulty and pain in swallowing from the infective process spreading to the gullet it is sometimes easier than might be anticipated to pass a soft rubber tube into the upper part of the œsophagus and administer fluid nourishment through it. Other complications must be dealt with as they arise. Death may occur from the virulence of the toxæmia with cardiac failure, or from pneumonia, or from cerebral symptoms, or impaired renal action. Bearing in mind the gravity of the toxæmic factor which overshadows the mere local lesion, the importance of early and skilled treatment by therapeutic inoculation measures cannot be too strongly insisted upon in all cases of pharyngitis of obscure etiology with spreading œdema, fever and albumen in the urine.

Chronic Pharyngitis.—It is usual to divide up chronic inflammation of the mesopharynx into two groups, the hypertrophic and the atrophic. The former, again, is subdivided into: (1) the simple catarrhal form with moderate thickening of the mucosa and hyper secretion; (2) the marked hypertrophic form with general thickening of the mucosa, submucosa and even muscular coats, more especially of the soft palate, folds of the fauces and salpingo-pharyngeal folds; (3) granular pharyngitis in which the thickening is limited to the islands of enlarged lymph tissue on the posterior wall and (4) lateral hypertrophic pharyngitis in which the salpingo-pharyngeal fold and the pharyngo-palatine folds are the regions enlarged. All these forms of hypertrophic pharyngitis are frequently associated with nasal obstruction and mouth breathing, and the relief of the former is often not only a necessary part of the treatment, but all that is necessary in the way of treatment. In many cases, however, there is either no marked nasal obstruction or the pharyngitis remains when the nasal lesion or lesions have been appropriately treated. The treatment must depend to a considerable extent on the exciting cause, and in few conditions is it so difficult as in a case of chronic pharyngitis to ascertain this with certainty, as the possible etiological factors are so many and varied and often remote. Local septic conditions of the teeth, mouth and tonsils may require attention. An elongated uvula, though a result of chronic inflammation, may become a factor in keeping it up by inducing cough and hawking. Pharyngitis is both caused and kept up by excessive discharges from the lower air-passages in the same way as it is from the upper air-passages. The pharyngeal mucosa is often sympathetically affected in various gastric disorders and in alimentary toxæmia; it is also frequently congested in cases of cirrhosis of the liver and in renal disease. Amongst more widespread morbid conditions must be mentioned gout, chronic rheumatic states, anæmia and sclerosis. Amongst extrinsic causes must be mentioned frequent exposure to inclement or irritating atmospheric conditions including the inhalation of irritating particles in connection with occupations. Tobacco-smoking and excess of ardent spirits no doubt in some measure account for chronic pharyngitis being much more common in men than women, more especially in hospital patients.

Treatment directed towards any one or several in combination of the above-mentioned causes may in fortunate circumstances lead to a cure without resort to local treatment. The latter is, it must be confessed, little more than palliative in many of the very chronic hypertrophic conditions, and no topical treatment can be expected to reduce a long-continued thickening of tissues which has extended even to the muscles, and chronic congestion is often equally intractable. When the latter is associated with constipation and portal congestion, considerable relief is often afforded by an alkaline coarse spray or douche, either hot or cold, in conjunction with the morning administrations of Carlsbad salts and purgative waters. These are the cases which are often successfully

dealt with at various spas such as Ems and also at Harrogate where the local treatment of the pharynx is carried out by the Ems method. In granular pharyngitis the reduction of the prominent islands of lymph tissue is generally regarded as a necessary routine treatment, but except where there is accompanying hyperæsthesia or paræsthesia which burning may blunt, it is doubtful if the cautery does much good. Iodine in the form of Mandl's solution is highly thought of by many practitioners, but I have usually found it disappointing. The same may be said of the local application with the brush of caustic solutions of nitrate of silver, protargol, argyrol, zinc chloride and copper sulphate. Astringents are certainly useful in sprays or douches in temporary relaxed conditions with excessive secretion. One or more of the various local anodyne and sedative remedies discussed in the sections dealing with sprays, douches, gargles and lozenges should be tried when there is pain, aching, soreness, irritation or cough. The latter in conjunction with hawking are especially liable to increase congestion. Finally it is important to rectify as far as possible any errors of diet and general hygiene; and faulty methods of vocal production, more especially in the case of professional voice-users, may require rectification at the hands of an expert in such matters.

Atrophic Pharyngitis in its advanced form is even more resistant to curative treatment than the markedly hypertrophic form, as the atrophied mucosa, together with its glands and blood-vessels, cannot be regenerated. Local palliative treatment together with general constitutional and hygienic measures give relief in some cases.

The disease is frequently an extension of the same pathological condition in the nose or else is associated with suppurative discharges from the nasal sinuses. Intranasal inspection and treatment, therefore, is of prime importance. Local measures in the pharynx are mainly palliative, and consist of removing, at least once or twice, and often many times, daily the sticky muco-purulent discharge and crusts which adhere to the mucosa of the posterior wall of the naso-pharynx. This is best effected with a brush charged with a paint containing either boro-glyceride, or menthol, or paroleine or glycerine. A creasote vapour beforehand is said to aid in the detachment by the brush. An alkaline coarse spray or douche, or menthol and thymol dissolved in paroleine applied through a special atomiser serves to finish up the toilette, and also to lubricate the mucosa and prevent readherence for some hours. Stimulation of the semi-atrophied glands by iodine paint locally and by iodide of potassium given internally undoubtedly relieves for a time in some cases, but this treatment should not be long continued as it may tend to increase the atrophic process. Menthol for the same reason should not be applied too strong and should be employed carefully and intermittently. Anæmia, dyspepsia, intestinal stasis and other departures from health, must be as far as possible rectified. Arsenic and arsenical waters are said to be occasionally of marked value, but must be administered with caution, well diluted and on a full stomach. There is considerable difference of opinion as to whether treatment at the sulphur spas really modifies or arrests the condition. It has been claimed that the bromo-iodine impregnated mud of Weston-super-Mare has a beneficial effect on young people suffering from atrophic rhinitis and pharyngitis who go to reside there.

SPECIAL THERAPEUTICS OF THE ŒSOPHAGUS

The treatment of morbid conditions of the gullet is mainly surgical rather than medical and of the nature of endo-œsophageal manipulative and surgical measures carried out with the *aid of the œsophagoscope*. General constitutional treatment is of limited usefulness, and often little more than expectant even in the more purely medical diseases such as those associated with nerve lesions and with the rare forms of œsophagitis due to the extension of septic œdema from the throat, to thrush, to diphtheria, to scarlet fever and to tuberculosis. On the other hand, in syphilis, which very exceptionally affects the gullet, the treatment is mainly medical in the first instance in active lesions and should be successful.

The following measures though largely manipulative may be considered as coming within the scope of this work—

1. The local application of sedatives and analgesics, and of lubricants, etc.
2. Endoscopic bougieing and the use of dilators.
3. The employment of feeding-tubes and of intubation.
4. Electrical methods.
5. The application of radium.

The Œsophagoscope as an Aid to Treatment.—The importance of the endoscope for the accurate diagnosis of lesions in the gullet is now becoming generally recognised, but it is almost as indispensable in treatment. Only by its aid should foreign bodies be removed, strictures be dilated and local applications made to ulcers, and radium tubes applied to cancers if accuracy, celerity and safety are to be combined. In many tolerant cases œsophagoscopic procedures

can be carried out by an expert under cocaine anæsthesia, aided by morphia and atropine; but in a considerable number of instances a general anæsthetic is either advisable or absolutely necessary where difficult or possibly dangerous manipulations have to be performed.

Local Sedative Applications. — Unlike the pharynx, local applications cannot be made either by unaided direct visual inspection or by the ordinary throat mirror as the gullet commences at the level of the lower border of the cricoid cartilage. For the mere application of sedatives and analgesics the use of the œsophagoscope is neither desirable nor necessary. Sprays of cocaine and powders of chloretone, orthoform and morphia insufflated into the back of the pharynx will be carried by the intermittently swallowed saliva down to the painful areas in the gullet and there exercise a local action. Another method, and one which insures a more lasting effect on the inflamed and ulcerating areas is to mix up one or other of the powders mentioned into a paste with bismuth oxychloride which tends to stick to the strictured regions, *e. g.* in carcinoma, for a considerable time, thereby effecting a more prolonged local action. I have noticed that patients suffering from ulcerating cancers or from ulcers resulting from the impaction of foreign bodies or from injuries, and from other forms of acute œsophagitis, have been relieved by the swallowing of bismuth paste which has been given in connection with a radiographic examination. Bismuth emulsion or bismuth made into a paste with a little water is therefore the ideal medium or base for the administration of analgesic powders.

Patients with stricture, especially the cancerous form, experience great discomfort and impaired swallowing power from the presence of a large quantity of frothy mucus and saliva in the dilatation above the stricture; relief can sometimes be obtained by administering the compound spirits of ether (Hoffman's anodyne) from 1 or 2 dr. being diluted with as little water as the patient will tolerate. This reduces the froth by diminishing surface tension, and it also has a local anæsthetic and antispasmodic action.

Lubrication of the gullet by means of liquid vaseline, refined petroleum and other oily fluids is sometimes useful in dysphagia by helping the bolus of food to slip through the strictured region. Anodynes can be advantageously added just before a meal.

Lavage daily with a solution of soda is very useful in large dilations above a stricture in cases where a pint or more of fluid, *e. g.* tea, is largely retained for an hour or so after swallowing on account of its only slowly trickling through into the stomach. Washing out the gullet above the stricture gets rid of solid food long retained which adds to the obstruction. In one case of cancer I removed a portion of mutton which had been retained since the last occasion that meat had been taken three weeks before. Lavage with Condy's fluid is also beneficial and sedative in ulcerative conditions and serves to diminish the characteristic fœtor in cancer. In cases where the stricture is not sufficiently tight to hold up fluids, I have devised a plan for efficient lavage which consists in sealing up the distal orifice of the red rubber tube and making another hole three or four inches further up; the terminal part of the tube is then passed into and tightly engaged by the upper part of the stricture, and fluid can be passed into the dilatation above and aspirated out again. Solutions containing peroxide of hydrogen should not be employed, as the frothing which takes place in the presence of blood, pus and débris may cause unpleasant respiratory obstruction by overflowing into the air-passages. Lavage is, of course, contra-indicated in perforations into the trachea or bronchi.

The Employment of Bougies. — The blind passage of bougies for the purpose of either diagnosis or treatment is now generally condemned by œsophageal experts, though the method is still largely resorted to by general physicians and surgeons and by family practitioners who fail to recognise that as a diagnostic agent it is inferior to the X-rays and rarely of any differential value, and is not free from an element of danger. It is true that fatal results and minor injuries are only exceptional occurrences, and it must be admitted that blind bougieing frequently affords great relief in many cases of stricture, but the risks are much greater than when the method is carried out aided by vision, through the œsophagoscope and the results are far better by the latter method, as it is possible to dilate up quite a tight stricture after localising its upper orifice by direct vision through the endoscope.

After, in the first instance, localising and dilating up a non-malignant stricture with the aid of the œsophagoscope it may be permissible in some cases subsequently to employ the bougie blindly; but this must be done with much circumspection even by experts. After per-endoscopic dilating by means of graduated bougieing not only is dysphagia relieved temporarily, but a stricture can be rendered sufficiently patent to allow of other methods of treatment such as temporary or permanent intubation or the application of radium; the latter is specially indicated in cancerous lesions of moderate extent. In very tight strictures a small gum elastic bougie two or three millimetres in diameter is gently insinuated through the stricture after the upper end of the latter

has been localised by direct vision through the œsophagoscope. Shifting the curve of the dorsal spine so as to straighten out the gullet will often aid this. When a small bougie has been successfully passed it is usually possible to dilate up the stricture so as to admit of one of eight, nine, or ten millimetres in diameter, when once the correct line has been got, by passing larger and larger bougies allowing each to remain a few minutes *in situ* if gripped. If great difficulty is experienced in getting at first a small bougie through, another small one should be passed alongside the other and allowed to remain a few minutes before withdrawing the first one and passing larger ones.

In America a strong thread with a shot at the end is much used as a guide. Several yards of thread are slowly swallowed, and when it has passed well into the intestines so as to become moored it serves as a guide when made taut for the passage of hollow bougies and dilating bags. I have found it useful to attach a dozen large shot to the thread so as to ascertain by the X-rays when they have passed sufficiently far into the ileum to allow of traction being made.

The patient in some instances should, if possible, be taught to pass soft rubber stomach tubes of suitable size himself two or three times daily after a tight stricture has been dilated up by endoscope bougieing with gum elastic sounds. These red rubber bougies can do no harm, but on the contrary may do much good if the patient can manage to pass them. When an organic stricture in the phreno-cardiac portion of the gullet has been dilated up by graduated bougieing or by a dilating apparatus, there is difficulty in the ordinary rubber feeding-tubes finding the upper orifice of the strictured lumen as the gullet above the stricture is often greatly dilated; in such circumstances I have employed with success a rubber feeding-tube with the orifice at the lower end sealed up and the tube filled with metallic mercury; if the patient makes the act of swallowing when the lower end approaches the strictured area the weight of the mercury will often greatly assist the passage of the tube into the stomach. If the patient can tolerate it the tube should be left *in situ* for half an hour, so as to exercise a further dilating effect.

Dilatation by Expanding Instruments.—The method of dilating up organic strictures by the passage of larger and larger bougies through the œsophagoscope at one sitting, has already been described. The advantages of continuous dilatation by the wearing of an intubation apparatus subsequent to bougieing will be dealt with more fully in a later section. Immediate dilatation by forcible methods are not largely resorted to. Brunings and Abrand employ expanding metal dilators, on the same mechanical principle as those used in the rectum and urinary passages in cicatricial strictures, more especially at the lower end of the gullet. They require to be used with great caution. I have myself resorted to this method on a few occasions, and in one case of fibrous stricture of the phreno-cardiac region of the gullet I caused a rupture below the diaphragm. The patient experienced great pain on swallowing a test draught of sterilised water a few hours after the dilatation, which was performed under an anæsthetic. He was therefore kept on nutrient enemata for three days and again tested when water caused no pain and food was resumed by the mouth. There were early symptoms of a localised abscess below the diaphragm; this, however, was not opened by laparotomy till it showed signs of having advanced nearly to the abdominal wall, as evidenced by œdema at the left costal margin near the sternum. The patient's dysphagia was, fortunately, very substantially relieved in spite of the mishap.

On the Continent Gottstein's pneumatic dilators are sometimes used; and in America Plummer and others claim great success in moderate tumefactive strictures near the cardia, the so-called cardiospasm, with rubber bags expanded by mercury forced in under pressure, but regulated by a manometer. Ruptures, however, have been occasionally recorded after these methods also, and all these forcible procedures are probably more dangerous than internal œsophagotomy. Dilatation by graduated bougieing carried out through the œsophagoscope under an anæsthetic followed by temporary intubation should be the method of choice in most cases.

Tubage and Intubation.—Both temporary and long-continued intubation are of great value in both acute and chronic strictures however caused. The simplest form of tubage consists in the passage of a soft red rubber feeding-tube through the narrowed region each time it is desired to feed the patient. This is particularly serviceable where there is painful swallowing in those exceptional cases such as acute œsophagitis due to microbic inflammation or to slight trauma after manipulations. It is also used after operations about the laryngeal orifice and deep pharynx, and in severe forms of dysphagia, due to tuberculosis or to paralysis.

The retention of a feeding-tube for a few days or for weeks or for more prolonged periods is employed not only to relieve dysphagia and even aphagia, but also for the "bougie effect" in bringing about increased patency for a time in chronic inflammatory and in escharotic and other cicatricial strictures, and also to maintain patency after the surgical treatment of stenosis in any form. It is also useful for

dilating up a cancerous stricture preparatory to the application of radium.

The retention of a small gum elastic catheter either temporarily or permanently was advocated by Krishaber at the International Medical Congress in London in 1881. This method was immediately afterwards adopted by Croft and by Durham with considerable success, and has been occasionally practised from time to time by others even up to the present day, as I can personally testify. Morell Mackenzie modified the method by using an entirely endo-œsophageal gum elastic tube, funnel-shaped at its upper end and of small calibre (6 mm. in diameter) which was held in position in the strictured part of the gullet by suspending strings attached to the teeth; this was the forerunner of the very valuable intra-œsophageal method of Charters Symonds whose well-known gum elastic funnel, much larger than Mackenzie's, is mainly retained in position by reason of its shape which prevents its being swallowed in many instances; strings should be attached to the teeth or elsewhere outside the mouth in cancer cases, to prevent its slipping down and becoming buried in the stricture and also to enable it to be withdrawn. Strings can now be dispensed with in tight non-malignant strictures as endoscopy enables one to select a funnel of such a suitable shape and size as will not slip down through the stricture, and with the œsophagoscope the funnel can easily be removed when it is desirable to insert a fresh one for purposes of cleanliness, or to substitute a longer or a larger funnel. The white-coated gum elastic materials used in France are an improvement on the usual English make, as they tend to retain their shape longer and do not become sodden so soon. Jackson and Guisez use rubber œsophageal funnels, and there might be an advantage in substituting celluloid or vulcanite for gum elastic material because less liable to decomposition; there might be, however, a disadvantage in their rigidity compared with the more pliable rubber and gum elastic tubes. Symonds' funnel has been of great service in many hands and in many cases, and modern endoscopic procedures, so far from tending to displace altogether this form of intubation in median thoracic strictures, have in reality widened the field of its applicability by enabling us to dilate strictures more efficiently to a size capable of admitting the lower tubular part of the funnel, and a whalebone or other guide (minus the handle) can be first inserted more easily through the œsophagoscope, thus facilitating introduction. Symonds' funnel, however, cannot at first at all events be employed in very tight strictures which are incapable of much immediate dilatation by endoscopic bougieing, though after the reduction of the obstruction by radium, or by wearing the styletted tube it may later become possible to insert the funnel with advantage.

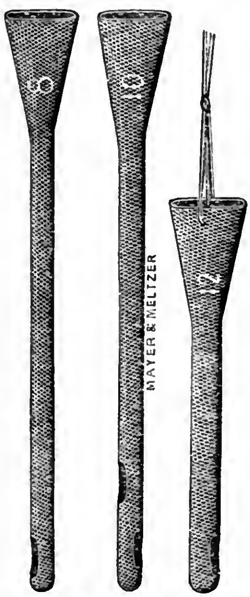

Fig. 13.—Symonds' gum elastic funnels for œsophageal stricture.

In stricture near the upper end of the gullet the funnel is not well borne, and in those near the phreno-cardiac region of the œsophagus the viscus is usually too dilated above to keep the funnel in position and prevent its being forced upwards out of the stricture. It is in these cases of tight strictures in whatever position, but especially in those near either end of the gullet, that an oro-œsophageal or an oro-gastric red rubber drainage tube of small calibre has proved such an efficient substitute for the funnel. Such a tube was, I believe, first employed in this country by James Berry over thirty years ago; the principle was a good one, but its introduction through the stricture was often very difficult even by the so-called railway method, and having no style, it was often either coughed or vomited up and then had to be re-introduced by a skilled hand. The tube was attached to the teeth or otherwise secured outside the mouth to prevent its being swallowed. This difficulty of introduction of a rubber tube was considerably reduced by Symonds when he brought out his modification of Berry's tube which somewhat resembles in shape a long Jacques urethral catheter, the passing of which is effected by means of a long thin whalebone guide lying along the *outside* of the catheter with the exception of the tip which is inserted into the eyelet; the guide can be removed

without disturbing the tube when the latter is *in situ*. Symonds' tube (which must not be confused with Symonds' funnel) has been used by me with success on several occasions; in some instances, however, it was either vomited or coughed up, the latter being especially prone to happen when there is a communication between the gullet and the air-passages: I was therefore led to devise a tube with a resilient style as a backbone, so to speak, to give it some measure of rigidity, and by which it could be attached to the teeth so that it could not easily be ejected by even the severest vomiting or coughing. At first I used a flat whalebone style passing through the whole length of a double tube. Such an apparatus was retained in a case of perforation for ten weeks. Later, I tried a soft silver flexible style instead of whalebone. The silver style tends to corrode and break in course of time, but its life is sufficiently long, varying from five to fifteen weeks. This styletted oro-œsophageal or oro-gastric intubation apparatus is generally easily introduced after endoscopic bougieing through the œsophagoscope, so that the question of putting in a fresh tube need not be considered on the grounds of difficulty. Patients can at first be fed with liquids only *through* the tube, but after a few days the "bougie effect" usually enables them to swallow fluids *by the side of the tube*, and later

Fig. 14.—Symonds' soft rubber œsophageal tube; a leaden plug, A, closes the proximal end, B; the hole placed laterally at the distal end is only faintly shown.

Fig. 15.—Showing whale-bone style, the end of which is inserted into the distal lateral hole of the Symonds' tube to facilitate introduction through the gullet stricture.

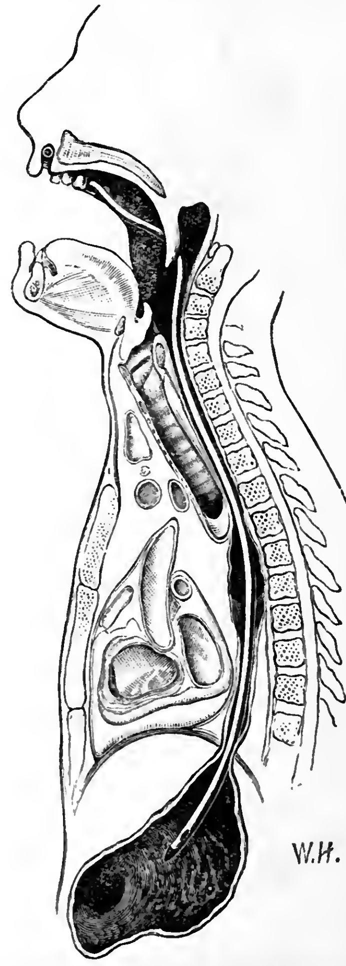

Fig. 16.—Hills' styletted oro-œsophageal feeding tube, which can be retained for a few days or permanently in œsophageal stricture; the proximal end can be secured to the teeth or to a denture.

soft food and even fat bacon, calf's head, tripe and onions and in some cases an ordinary meal can be got down quite easily in this manner. Although in advanced cases the tube has to be retained permanently, in others it can be left in for a week or two until owing to the bougie effect the patient swallows fairly well by its side, when it can be advantageously removed until the dysphagia again becomes troublesome. Of course patients are always very glad to get rid of the apparatus for a time, but it is generally well borne, and in only a few instances of cancer at the mouth of the œsophagus and deep pharynx do I remember serious pain and discomfort being complained of. The continuous bougie effect is of great importance because the patient frequently manages to swallow his saliva and thus is relieved from the constant expectoration of frothy mucus which sometimes amounts to many pints in one day and which is often such a distressing complication after gastrostomy. In cases of perforation the method of feeding entirely through an oro-œsophago-gastric intubation apparatus is specially indicated for permanent use in order to prevent liquid nourishment entering the air passages and causing violent fits of coughing; these cases always suffer from a good deal of coughing and expectoration due to swallowed frothy saliva, but the discomfort is only moderate compared to that brought on by fluids entering the air-passages. In mid-thoracic strictures with perforation a Symonds' funnel is in those cases where it can be inserted, to be preferred to a long oro-œsophageal or an oro-gastric tube, as the funnel shuts off the alimentary route from the air-passages.

Electrical Methods.—Treatment by electricity is little employed in the gullet. It is not of much service in the rare cases of paralysis of central origin. Functional neuroses are usually held to be of common occurrence, more especially in the form of œsophagismus and cardiospasm. The writer with a large œsophagoscopic experience has not found an unequivocal case of primary spasmodic stricture, though secondary spasm of the gullet evidenced by painful colic is often met with as a symptom of temporary tumefactive or of permanent organic stenosis when food is arrested. True functional dysphagia is usually due either to paresis or to a minor degree of subacute tumefactive œsophagitis. Paresis is best treated by bougieing, which has a stimulating action akin to the application of a brush or swab dipped in menthol paint in functional paresis of the pharynx and larynx. In peripheral neuritis, whether functional or otherwise, *faradism* would only be of possible service in the upper third of the gullet, where there are striped muscular fibres. In the lower two-thirds of the gullet, where the musculature is unstriped, faradism is useless and ordinary galvanism dangerous unless applied with special precautions to avoid an electrolytic action. The *sinusoidal current* is, however, free from danger, but any good result occasionally following its application may be partly due to bougie effect and partly to suggestion. It is probably useless in restoring tone to a dilated œsophagus which is regarded in some quarters as its chief indication.

Ionisation has been carried out very occasionally in organic strictures of the gullet, but the great difficulty in limiting its field of action seems almost to contra-indicate its employment. The same remark applies in a lesser degree to other destructive electrical methods, such as electrolysis, galvano-cautery and diathermy. The electrolytic method is, however, largely used by so experienced an œsophagoscopist as Guisez in fibrous strictures as an adjunct to forcible stretching.

The X-rays.—Whilst Roentgen radiography should be employed in most cases of suspected œsophageal disease for diagnostic purposes, it is little used therapeutically for the reason that the major part of the viscus is enclosed in a bony cage and is remote from the surface. In a few instances, however, it has been claimed that dysphagia due to carcinoma has been substantially relieved by this method of radiotherapy, more especially in lesions of the upper third of the gullet.

Radium Therapy.—The radio-active rays of radium salts and of radium emanation and of mesothorium have now been given a trial in a considerable number of cases of malignant disease of the gullet. The method was first tried by Exner in 1904 with short applications of lightly screened radium bromide. He and Einhorn claimed palliative results. It was not, however, until Guisez of Paris in 1908 commenced to employ radium frequently in gullet cancer in conjunction with Dominici that this therapeutic agent was given an adequate trial. As the result of the publication of some encouraging palliative results by Guisez in 1909, I was induced to give the method a trial in the summer of that year, and I reported my first series of twenty-one cases in February, 1911. (See *Trans. Med. Soc. Lond.*, Vol. XXXIV. pp. 211–222.)

I felt justified in claiming temporary disappearance of naked-eye evidence of growth in three cases and remarkable improvement both objective and subjective in seven cases. There was also apparently some substantial improvement in seven other cases which might or might not have been due in some of them to the "bougie effect" of the radium apparatus in relieving the stricture. One of these cases, in which the diagnosis was based on œsophagoscopic and

microscopical examination, is still living and in very fair health, eight applications of radium having been made at varying intervals during the last four and a half years. After the

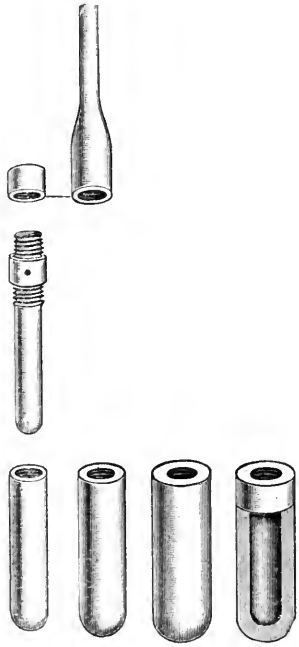

Fig. 17.—Finzi's Platinum tube containing 100 mgrms. of radium with style attached to the cap and additional metal screens, one of which has a window.

second application the fungating mass disappeared and the ulceration healed; there has been regrowth and ulceration observed on three occasions since. The swallowing has never been quite normal during the intervals when there was disappearance of objective signs as the lumen remained narrowed somewhat by fribrosis following radium. Another application had to be made quite recently.

The broad lines of technique employed by experts using radium in cancer of the gullet are the same. (1) The length of the stricture is ascertained by radiography after swallowing bismuth paste or thick bismuth-impregnated bread and milk or porridge. (2) The œsophagoscope is then used to confirm the diagnosis and explore the cancerous area as far as possible; for this a general anæsthetic is often desirable. (3) If the stricture is too tight to admit of the radium apparatus, it is sufficiently dilated up by graduated bougieing through the œsophagoscope, a procedure which can be carried out more thoroughly under a general anæsthetic. Should the stricture not be dilatable sufficiently to take the radium tube, the latter is passed down through the œsophagoscope as far as it will go and allowed to sit on the narrower part of the stricture.

The practice of œsophagoscopists have differed in matters of detail. Some insert the radium tube in a hollow gum elastic catheter and allow this to remain *in situ* for two or three hours or more. Others insert the radium tube through the endoscope into the stricture with slender forceps and allow it to be *held* in the stricture. The tube is enclosed in rubber as described in the special section dealing with radium in the pharynx (*q. v.*), string being attached to prevent displacement, to withdraw the apparatus at the end of the application or to draw it up to a higher portion of the stricture. This was the method followed by me in earlier cases, and it has the advantage over the styletted apparatus which Finzi and I have largely adopted during the last three years in that it causes less discomfort to the patient than when a style passes through the pharynx and is attached to the teeth. One of the advantages of the styletted apparatus is that it can be more speedily and accurately inserted under cocaine anæsthesia; and we have found it indispensable in our more recent practice of immediately checking the position of the apparatus by means of the X-rays and a bismuth meal. If the radium tube is seen on the screen to be not quite in position it can be

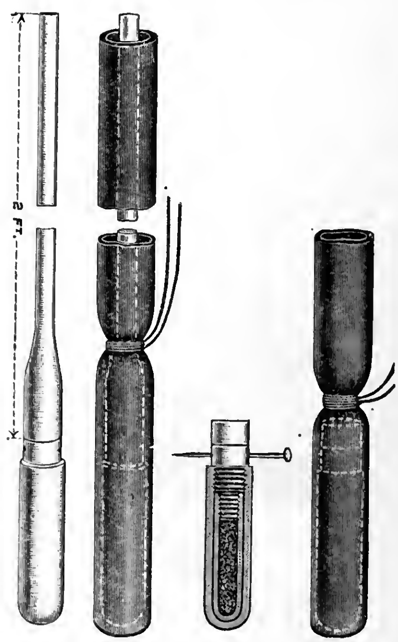

Fig. 18.—Finzi's apparatus with rubber covering.

accurately raised or lowered by means of the soft silver style. When this radiographic check is not used, one has to rely on very careful measurements made before inserting the tube, as to the depth from the teeth at which it is

to be inserted; this distance has to be carefully marked off on the style by a silk ligature. In long strictures the radium tube can be allowed to remain *in situ* in the lower part of the stricture for from eight to twelve hours and then pulled up the length of the tube for a further period into the upper part.

In conjunction with Finzi I have sometimes used two tubes arranged tandem and on one occasion we inserted three tubes thus arranged one above the other. Such a long stricture

FIG. 19.—Radium tube attached to a flexible silver style, which is inserted into a malignant stricture with the aid of Hills' œsophagoscopic tube; the lateral slot in the latter enables it to be withdrawn without disturbing the position of the radium apparatus.

is, however, usually unsuitable for radium treatment.

When the patient is intolerant to endoscopic manipulations the apparatus can be inserted under a general anæsthetic. This can be done at the initial examination when dilating up the stricture, but has the disadvantage that it cannot be carried out in the X-ray room in order to check the exact position of the apparatus; when the stricture is too tight after dilating up to admit of the passage of the tube through it there is, of course, no advantage in resorting to subsequent radiography.

As regards the length of exposure to the rays when using the amount usually employed, viz. 100 mg. of radium salt (measured as pure radium bromide) or its emanation equivalent, Guisez, who has had considerable experience, recommends in his book on *Diseases of the Œsophagus*, published in 1911, an application of four or five hours every other day until a total of twenty-four to thirty hours is attained. He uses silver screens amounting to $\frac{8}{10}$ of a millimetre in thickness enclosed in a gum elastic sound. Under the guidance of Finzi I have used screens of either silver, lead or platinum of from $1\frac{1}{2}$–$2\frac{1}{2}$ mm. in thickness enclosed in rubber 1 mm. thick. Our present practice for 100 mg. is to use a platinum screen, 2 mm. thick, enclosed in rubber and to allow the tube to remain at one spot for twelve hours at the lower part of a long stricture. If the apparatus is then raised, say 2 or 3 cm. to act on the upper part of the stricture, it can remain in another twelve hours, if the patient will tolerate it; if not, another application is made after an interval of two or three days. No fresh application is made earlier than six weeks—that is to say, after all reaction has passed off. This is in accordance with the practice of Dominici, and has been followed also by Knox and by Pinch. An œsophagoscopic examination is made before repeating the treatment. A second application is usually called for at the end of six weeks in cases where there is marked or moderate improvement; and subsequent applications are made according to local appearances. The treatment should not be persisted in when no very obvious good is effected.

If a thinner screen is used in tight strictures, and especially when a window-screen is employed in cancers, limited to a lateral segment of the tube of the gullet, then the exposure should not exceed six or eight hours on end.

There is rarely any difficulty in inducing the patient to tolerate the apparatus for twelve hours when it has been inserted under a general anæsthetic, as the drowsiness can be kept up by a judicious employment of morphia and atropine. The same sedatives, or else scopomorphine, are essential when the apparatus is inserted under cocaine anæsthesia. Some patients manage to swallow water fairly well with the styletted apparatus in position, but in other cases if thirst is complained of this should be relieved by the sucking of ice or of lemons. I have only on a few occasions kept the radium tube in position for such long periods as twenty-four and twenty-eight hours, but even then have not had recourse to rectal feeding. After removal of the apparatus more or less soreness behind the cricoid is usually complained of, but passes off in a few days and rarely increases dysphagia to a marked extent.

The contra-indications include an advanced stage of the disease with involvement of several inches of the gullet, the penetration of the

growth into the lumen of the trachea or bronchi, or invasion of the lungs, marked involvement of the glands of the neck or mediastinum, and lesions of the phreno-cardiac portion of the gullet with probable extension to the stomach. Patients who are greatly debilitated or who have undoubted cardiac weakness are unsuitable for the employment of either local or general anæsthesia and would be unable to tolerate the apparatus for a sufficiently long exposure. Chronic bronchitis I regard as another contra-indication in elderly and weak subjects. In fact, patients should be in fair general health and the strictured area should not be more than 5 or 6 cm. long. Fungation is not a contra-indication.

Diet.—The question of appropriate diet in various types of stricture is of great importance, but space does not admit of its adequate discussion. Milk, egg and milk, thickened soups, purées, minced tripe, calves' head and fat bacon, custards and ice-creams can usually be swallowed in intubated cases *beside* the tube; liquids only should be given *through* the tube. In some unintubated cases fish tends to stick more than well-masticated butcher's meat.

Alimentation by the Rectum.—Rectal feeding is a valuable temporary expedient in acute œsophagitis and ulcer—whether due to traumatic and escharotic causes or not—in rupture from vomiting, in the case of impacted foreign bodies where it is desired by rest to reduce tumefaction caused by unskilled efforts at removal and preparatory to resorting to œsophagoscopic measures, in some cases of carcinoma more especially to render the patient more fit for gastrostomy, and also to supplement alimentation *per vias naturales*, where swallowing is either difficult or painful. It is also usefully employed for two or three days after excisions of portions of the pharynx, larynx and œsophagus, where regurgitation and vomiting of food may soil the incised tissues before the lymphatics are sealed up.

The possibilities and limitations of rectal feeding is fully dealt with elsewhere, but it may be well to repeat here that Langdon Brown has shown that the nutrient enemata containing peptonised proteids, which have hitherto been so largely employed, have no nutritive value worth mentioning and are little superior in that respect to mere saline enemata which relieve thirst, increase the volume of blood in the vessels after hæmorrhage and are less messy and free from a tendency to decomposition. Proteins are not absorbed as peptones in the lower alimentary tract, but as amino-acids; peptonisation, therefore, does not go far enough to render proteid enemata absorbable by the lower bowel.

Pancreatised milk and dextrose form the best ingredients for nitrogenous rectal feeds. Rendle Short gives the following directions for their preparation: "To a pint and a half of milk boiled and cooled add ½ oz. of some reliable pancreatic fluid or four pancreatic tablets; keep in the incubator twenty-four hours; add ½ oz. of pure dextrose. Give 5 oz. every four hours, or if the patient can retain it 10 oz. every eight hours." Where the patient is very thirsty, whether from severe loss of blood, or otherwise, a saline enema can be given in the first instance and the nutrient injection resorted to later.

The Treatment of the Commoner Diseases of the Œsophagus

Neuroses of the Gullet.—Organic paralysis is not often met with, but when present is usually of central origin, *e. g.* hæmorrhage and tumours of the pons and medulla, bulbar paralysis, multiple sclerosis, locomotor ataxy, general paralysis of the insane, and, in short, in any lesion affecting the deglutition centre. The use of a feeding-tube is necessary in advanced cases, and beyond this local treatment, *e. g.* electricity, is of little value. The latter, however, may be tried in the form of sinusoidal current in those rare cases of peripheral neuritis of the plexus gulae occurring after, *e.g.* diphtheria and influenza. For general constitutional treatment the section on *Disorders of the Nervous System* can be consulted.

Spasmodic Paroxysms may occur in association with pharyngeal spasm as a symptom of certain general diseases such as rabies, tetanus, epilepsy, chorea, strychnine poisoning and hysteria; the appropriate treatment for which is dealt with elsewhere. Primary *functional spasm* is usually, but probably erroneously, held to be a common cause of intermittent dysphagia. Painful colic is the characteristic mark of spasm in the intestinal tract, and unless this is present the diagnosis of spasm is almost certainly unwarranted, and when present the colic is almost invariably *secondary* to an organic lesion of the gullet. True functional dysphagia is usually painless and due to paresis rather than to primary, *i. e.* idiopathic, spasm.

In functional paresis bougieing has a stimulating effect in some cases, and this can be reinforced by the intra-œsophageal employment of the sinusoidal current. The treatment of secondary spasm consists in relieving the cause which is generally of the nature of acute or subacute inflammation causing stenosis or is due to the presence of a well-established organic stricture. The use of the bougie relieves by reducing the stenosis. A number of conditions have been inaccurately grouped together under the heading of primary cardiospasm. Gottstein mentions the following: (1) kinking or angulation of the

lower or phreno-cardiac portion of the œsophagus; (2) congenital defects; (3) atony, *i. e.* paresis, either fundamental or organic; (4) œsophagitis with temporary or permanent anatomic narrowing near the cardia; (5) genuine cardiospasm. In my experience either paresis, angulation, tumefactive œsophagitis, or a permanent anatomic stricture are the conditions found on œsophagoscopic examination, and for these the term cardiospasm is a misnomer. The above conditions are relieved by bougieing which would only induce and aggravate primary spasm.

Acute Œsophagitis.—This probably is never primary, but secondary to acute stomatitis, to septic pharyngitis, to thrush, to gastritis, or to continued bilious vomiting (two cases seen by the writer); it may be symptomatic, as in impaction of foreign bodies, in traumatic and escharotic œsophagitis and in ulceration from typhoid fever, smallpox and diphtheria, and in peptic ulcers near the cardia. There is often fever, and nearly always burning pain, aggravated by swallowing, which latter is difficult. Stiffness and tenderness to pressure in the neck, profuse salivation and expectoration of frothy mucus were constant symptoms in the few recorded cases. The absence of marked attacks of spontaneous spasms in the pharynx and neck distinguishes it from hydrophobia, but it is not always possible to exclude deep peri-œsophageal abscess even by œsophagoscopy. Ice, cocaine and chloretone locally, and morphia and atropine hypodermically, abstinence from food by the mouth for a day or two and the administration of saline rectal injections may give relief. Feeding through a stomach tube, or the wearing temporarily of an intubation apparatus, is indicated where swallowing is extremely difficult and painful, and more especially if there is ulceration, provided that the wearing the tube does not itself cause much pain. The general constitutional treatment depends on the cause. In septic cases with fever, autogenous vaccines are indicated.

Fibrous Stricture of the Gullet.—This may result from any condition causing ulceration, for example, traumatism from unskilful instrumentation, ulceration resulting from impacted foreign bodies, from swallowing corrosive fluids, from syphilitic lesions, and also from general hypertrophic thickening in the phreno-cardiac portion of the gullet; the latter is usually obscure in origin, but may have been preceded by definite œsophagitis due to diphtheritic lesions or to peptic ulcers in association with gastritis. I have never known primary spasm to be the cause. Dysphagia is the most prominent symptom, with regurgitation of food, the amount and character of which varies with the degree and site of the superimposed dilatations; œsophagoscopic measures will determine the site, degree and nature of the stricture; the amount of dilatation above, and the length of the stricture being best shown by radiography in conjunction with a bismuth meal. When resulting from the swallowing of corrosive fluids the stricture may be so long and tight that endoscopic dilatation by bougies may be useless and gastrostomy may then be unavoidable; in most cases, however, endoscopic dilatation by bougies and reinforced in some cases by the employment of Brünings' or Abrand's dilator, followed by temporary intubation, will afford relief for months or years, when these measures may have to be repeated.

Internal œsophagotomy performed through the endoscope is rarely advisable or called for, is not free from danger, and is applicable only to very short, tight annular strictures. External cervical œsophagotomy is practically an obsolete method, and is more dangerous and less convenient for the patient than gastrostomy. In tight strictures of the phreno-cardiac region, gastrostomy can be supplemented by digital dilation and followed by tubage.

Lavage of the dilated gullet is always useful, especially where there has been erosion from continuous retention of decomposing foreign matter. Mercury and iodide of potassium are, of course, indicated in syphilitic cases, but such measures as fibrolysin injections and ionisation are probably not worth the trouble involved in their employment. The measures to be relied on are dilating up with bougies through the œsophagoscope followed by continuous dilation for a week or two by wearing an intubation apparatus. This treatment may have to be repeated periodically. Stretching the strictures by expanding metal dilators and by pneumatic and hydrostatic bags is rarely either necessary or advisable.

Dilatations of the Œsophagus.—A general ectasia of the gullet occurs above any stricture which is of long duration, *e. g.* in cicatricial stricture, in long-impacted foreign bodies, and in cancer. Congenital, idiopathic and spasmodic dilatations are described, but the evidence of their existence is, in the writer's experience, unconvincing. In diffuse dilatation, when no anatomic narrowing of the phreno-cardiac gullet exists, the explanation is probably to be found either in angulation, kinking or in general paresis of the gullet, with want of co-ordination of the act of deglutition, the cardia not opening up normally; the latter is better explained by paresis than by hypertonic spasm. True dilatations are usually either fusiform or globular, but in carcinomatous stricture the lower part of the ectasia may appear irregular in the X-ray photograph after a bismuth paste meal. Dilatations of the gullet are often

associated with regurgitation (œsophageal vomiting). Palliative treatment consists in dealing with any stricture by dilatation, and with the paresis, if present, by lavage and the employment of the sinusoidal current. Ordinary galvanism is dangerous in unskilled hands.

Malignant Stricture of the Œsophagus. — Epithelioma is the commonest form, but spheroidal-celled carcinoma and endothelial sarcomas are met with; colloid cancer and true sarcomas are very exceptional. The disease may originate in any portion of the tube, but the constriction at the entrance to the gullet, opposite the left bronchus, and at the phrenic constriction, where the tube passes through the diaphragm, and at the cardiac orifice are the favourite sites. The *revealing signs* of malignant stricture are late; *slight* dysphagia is the earliest symptom; and this often appears suddenly, as after a piece of meat becoming impacted, the patient never afterwards being free from slight difficulty with solids, though liquids may pass freely for a time; the dysphagia is usually progressive and rarely intermittent; it may never interfere with the patient taking sufficient nourishment *per vias naturales ;* on the other hand, complete aphagia may ensue, necessitating intubation or gastrostomy. By radiography we can observe the level of the upper and lower ends of the stricture and its calibre to a certain extent, and also the amount of dilatation above the stricture, but it is only by a direct œsophagoscopic examination that the nature of the stricture can be determined with anything approaching certainty. This should always be resorted to; the writer has found on six occasions that the diagnosis of cancer, which was made by others, and seemed to be justified on clinical grounds, had to be abandoned after an endoscopic inspection had shown the stricture to be non-malignant and therefore amenable to endo-œsophageal treatment. The endoscopic inspection should also include an examination of the larynx, trachea and bronchi, as extension to these areas, before there are any obvious pulmonary symptoms, should influence not only the prognosis, but also the treatment for such conditions; for if the air tubes are invaded the employment of radium, for instance, is contra-indicated, and intubation methods are especially suitable.

The treatment of primary gullet cancer is practically always merely palliative for the relief of dysphagia and pain. The only cases in which operation has hitherto been successful were in all probability not instances of primary disease, but of invasion cancer from the pharynx, and in these instances Solis Cohen's and Gluck's types of operation, viz. total laryngectomy together with partial excision of the deep pharynx and a small segment of the adjacent cervical œsophagus, have often been successful; when the larynx, the posterior surface of the cricoid plate and the pyriform fossæ are free from disease the larynx need not be removed. The technique is well described by Trotter in his recent Hunterian Lectures. Œsophagectomy alone, whether of the cervical œsophagus as first practised by Czerny, or of the thoracic, or of the abdomino-thoracic œsophagus by thoracotomy after the methods of Sauerbruch, von Hacker, W. Meyer and others, had until recently no permanent or even temporary cure to its credit. In 1913, however, Torek, of New York, removed a portion of the thoracic gullet for cancer, with survival of the patient after an extensive posterior thoracotomy; and another operative survival has lately been reported. With early recognition by means of the more general adoption of exact endoscopic methods of diagnosis with the œsophago-gastroscope, together with improvements in operative technique, an occasional successful œsophagectomy may be expected.

Killian has claimed to have diagnosed and successfully removed a small sarcoma of the gullet by endo-œsophageal measures through the œsophagoscope, but it will probably be long before another such cure is recorded.

Palliative gastrostomy is the only external operation extensively practised; with the more general resort to intubation rendered possible by the recent adoption of endoscopic methods, the number of cases gastrostomised should be largely reduced. It is specially indicated where intubation is often too dangerous or impossible, as in long, tight strictures, more especially in the phreno-cardiac region. Gastrostomy should not be put off till the patient is in a thoroughly debilitated condition; on the other hand, some surgeons, in the writer's opinion, resort to gastrostomy at too early a stage, when intubation and other measures, if œsophagoscopically carried out would be quite sufficient for the comfort of the patient.

Iodides, iodipin, fibrolysin, like serums, vaccines and enzymes, are not often even of temporary value. Some measure of success has been claimed for colloidal preparations of selenium and of copper. Of drugs acting locally spirit of ether breaks up frothy mucus in the gullet by reducing surface tension. Astringents, like adrenalin, cocaine and turpentine, are of little use; local anodynes, such as morphia, chloretone and orthoform, combined with bismuth emulsion are sometimes useful for pain in cancer high up; they rarely, however, enable one to dispense with hypodermic injections of morphia, atropine, etc., in very painful cases.

Lavage of the gullet, in cases of dilatation

above a stricture, is the best means of removing decomposing substances, such as food residues and the products of ulceration, but glycerine of boric acid and of carbolic acid, sanitas and similar preparations are also useful as disinfectants and deodorants. Peroxide of hydrogen is contra-indicated as it may cause respiratory embarrassment.

Caustics are generally inadvisable, even when applied endoscopically to tight strictures and diathermy; ionisation and carbon dioxide snow have not as yet had any extensive trial. Relief of dysphagia by X-rays has been claimed in a few instances.

Blind use of bougies undoubtedly gives relief to dysphagia, but is not free from danger even in expert hands, and should be abandoned in favour of endoscopic bougieing, which is a much safer and more efficient procedure in every way—but with intubation periodical bougieing is unnecessary.

Symonds' gum elastic funnels are extremely useful when the gullet can be endoscopically dilated up to a sufficient size to permit of their insertion. They are especially indicated in perforation into the air passages, but cannot be used in stricture near either end of the gullet. Berry's and Symonds' rubber tubes are also useful, but have been largely superseded after much experience by the writer in favour of his styletted oro-œsophago-gastric tube, which can be fastened to the teeth and retained temporarily or permanently without any fear of being coughed or vomited up; it is inserted through the œsophagoscope after dilating up the stricture. The patient is first of all fed with liquids by a funnel through the tube, but later liquids and frequently solids pass readily by the side of the tube owing to the continuous bougie effect on the stricture. This form of intubation apparatus is equally suitable for cases when the stricture is at the entrance to the gullet or well in the thorax; it must, however, be passed with caution in malignant stricture of the phreno-cardiac portion of the œsophagus, as the gullet here takes a curve forward and to the left, and the lesser sac of the peritoneum has been more than once perforated by instrumentation in this region.

The most recent and probably the most valuable palliative measure which has been employed in cancer of the gullet is the application of radium salts or of radium emanation suitably screened. The remedy is like most therapeutic procedures, an uncertain one, but where the disease is not very extensive, the radium tube can be accurately inserted into the stricture by means of the œsophagoscope aided by the X-ray screen, and the results, though probably only temporary, are certainly often most effectual, not only in causing subjective relief of symptoms and temporary cessation of the dysphagia and expectoration, but also in bringing about widening of lumen, healing of ulcers, and sometimes even leading to the temporary disappearance of all naked-eye objective evidence of disease. The writer has employed this method in conjunction with Finzi in over thirty cases of gullet cancer, using from 50 to 200 mg. of radium salt screened in lead, silver or platinum of from $1\frac{1}{2}$ to $2\frac{1}{2}$ mm. in thickness, and in more than half the number there was either remarkable or very substantial improvement. [See pp. 281–284.]

W. H.

DISEASES OF THE STOMACH

The basis of the rational treatment of diseases of the stomach is the proper conception of the disturbances of functional activity which therein obtain, and the capacity of our therapeutic measures to restore these to normal limits.

Disturbances of functional activity are immediately responsible for the subjective manifestations of gastric disorder, the phenomena which obtrude themselves unpleasantly upon the consciousness of the individual, and they may or may not be associated with, and dependent upon, some structural change in the organ. On the other hand, it is highly probable that any structural change will remain subjectively latent unless it is associated with a perversion of functional activity beyond the normal limits.

In medical treatment, our therapeutic measures are directed immediately to the restoration of such disordered function, and very remotely to the reparation of any morbid structural change, and that only by neutralising or removing such conditions as conceivably interfere with natural reparative processes.

Dyspepsia.—It is convenient to employ this term to comprehend the subjective manifestations of all the various perversions of gastric functional activity, however arising, rather than to limit it to any particular types of doubtful origin.

Dyspepsia may be of a (1) *Simple Type*—depending wholly upon a lack of correlation between the digestive requirements of the ingesta and the functional capacity of the stomach.

(2) *Reflex Type*—depending upon the existence of some lesion more or less remote from the stomach, and a more or less susceptible nervous reflex mechanism.

(3) *Organic Type*—depending upon some structural change in the stomach itself.

With a view to treatment, it is necessary at the outset to determine to which of these types any case of gastric disorder belongs.

Simple Dyspepsia

This condition depending upon either the dietetic abuse of a normal gastric mechanism or of one enfeebled by some general or constitutional condition, by anomalies in the quantity or quality of food, its preparation, its mastication or its ingestion, demands a careful correlation of the diet and the functional capacity of the stomach as the essential factor in its treatment.

In all cases the mouth and teeth should be carefully examined, and any defects in the number or relations of the teeth, painful caries and pyorrhœa, should be remedied.

It is useful to get the individual to relate in detail the diet of one or two typical days, noting times of meals, the length of time given to them, the doings of the individual immediately before and after meals, the kind and amount of food taken. In this way it is generally possible to determine the essential factors in the dyspeptic disturbance. Arriving at meals in a physically or mentally exhausted condition, immediately leaving for further strenuous occupation, "bolting" food in an imperfectly masticated condition, the taking of "nips" of alcohol or too-frequent "appetisers," of excessive quantities of tea or coffee, of rich, highly seasoned foods, of made dishes, or of foods recognisedly difficult of digestion, or the abuse of tobacco. The re-ordering of the daily life of the individual, insisting upon regularity of meal-times, adequate rest before and after meals, thorough mastication, the substitution of simple, plainly cooked foods for made dishes and indigestible viands, cutting down the starchy foods, the substitution of split toast and crust for bread and potatoes, the elimination of alcohol and coffee and of tea and tobacco in excess, generally suffice to put an end to the dyspepsia. The difficulties of treatment are often found to be not in the measures to be employed as in persuading the individual to carry them out.

Should symptoms of gastric irritability still persist after the reorganisation of the diet, these may be met by the administration of takadiastase immediately after food, and of a simple bismuth and soda mixture some ten or fifteen minutes later.

A more severe type, which in its most developed form constitutes a variety of the so-called nervous dyspepsia, is associated with the nervous exhaustion entailed by mental worry, sexual excess, etc. It calls for a very strict supervision of the daily life of the individual, a complete rest at some quiet inland resort, preferably of a fairly high altitude, a course of physical exercises, or of massage, and the administration of bromides along with bismuth and soda after food.

The second variety of simple dyspepsia, *atonic, asthenic or myasthenic dyspepsia*, depends on a perversion of the functional activity of the stomach associated with and secondary to some general or constitutional condition, exhausting illnesses, anæmia, constipation (cæcal stagnation) neurasthenia, constitutional asthenia (Stiller). The disordered functional activity chiefly concerns the motor functions of the stomach, viz. deficient tonic contraction of the body (peristole); the peristaltic activity of the pyloric portion, on the other hand, shows curious variations, periods of normal or excessive activity with spasm alternating with periods of deficiency in which stagnation occurs. The secretory activity of the stomach also varies, in most cases it is about the lower normal limits, in some it is somewhat above normal, in a few it is considerably depressed.

In the treatment of this variety the general condition must be actively dealt with, and an improvement in the general nutrition is invariably indicated; this has to be met by such careful regulation of the dietary as will provide the greatest possible nutrition with the least strain on the stomach. In severe cases, and even in slight cases where possible, the patient should be confined to bed, or at least the horizontal position should be assumed for half an hour or more after each meal. In this way much strain is taken off the stomach, and its emptying facilitated. Washing out the stomach last thing at night with warm normal saline is of advantage when there is stagnation, in so far as it ensures a few hours' absolute rest for the stomach. Abdominal massage each day, and general massage two or three times a week, should be employed to improve the tone of the stomach and the general condition. The diet should be divided into four or even five small meals a day, and should consist of junket, custard, jellies, lightly cooked eggs, stewed tripe, steamed white fish, chicken, pigeons, lightly grilled and minced beef or mutton, purée of potato in small quantities, spinach, turnip-tops, split toast, crust, rusks, well-cooked sago, etc. The food should thus be semi-solid in character, and the amount of fat restricted, owing to its inhibitory action on gastric motility. Of fluids, two small cups of weak tea may be allowed, but coffee and cocoa should be avoided; in addition, the patient should take half a pint of hot water each morning, to which may be added a teaspoonful of Carlsbad salts if the bowels are constipated. Of drugs, strychnine is most generally employed for its reputed action in improving the motility of the stomach, and it may be administered in combination with dilute hydrochloric acid (20 min.) after food, in those cases where the secretory activity is also deficient,

ɪr as Tinct. Nuc. Vom. with Sod. Bicarb. and ĭod. Brom., where the secretion is excessive.

Physostigmine also exerts a stimulating action n the gastric musculature, and may be given a doses of $\frac{1}{100}$ gr. once or twice a day. Should he bowels be obstinately constipated, simple oap and water enemata and petroleum are ɪreferable to powerful aperients.

Subsequently the patient should endeavour o maintain an improved general condition by egulated physical exercises.

Reflex Dyspepsia

The gastric functions may be disordered eflexly by a lesion situated more or less emote from the stomach itself. The two ssential factors in the production of this ondition are the existence of such a lesion and n increased susceptibility of the reflex nervous nechanism. These may vary indirectly, thus ome lesions, as a duodenal ulcer, may assert heir existence through a nervous mechanism ttle more susceptible than the normal; whilst thers, as some ileo-cæcal lesions, may remain ıtent until the susceptibility becomes greatly xaggerated. There is little doubt that many ıch cases were formerly classed as nervous yspepsia. The chief lesions are: duodenal lcer, cholecystitis, chronic appendicular lesions, eal kinks, chronic ileo-cæcal inflammations, æcal and colonic stagnation, diseases of the enerative organs in females, mobility of the idneys, diseases of the central nervous system.

In such conditions the objective of medical reatment is to counteract or neutralise the ınctional disturbance in the stomach, to epress the susceptibility of the reflex nervous nechanism, and to establish such conditions s will be favourable to the resolution or uiescence of the maintaining lesion. Complete nd permanent relief of the reflex gastric isorder often calls for operative intervention or the eradication of the responsible lesion, ut even in this latter contingency it is well to emember that with a nervous mechanism ufficiently unstable, the healing process followıg operation may suffice to maintain some egree of gastric disorder.

The particular disorder of functional activity 'hich characterises this type consists in exessive activity, both of the secretory and the notor functions of the stomach—the so-called ypersthenic dyspepsia, or *acid dyspepsia* ıcluding *hyperchlorhydria, hypersecretion*, alinentary and continuous, and gastrospasm and ylorospasm, all of which are, in all probability, arying degrees of one and the same type of ınctional disturbance.

The peculiar intermittency which characterises this type of dyspepsia depends in some cases n the varying susceptibility of the reflex nervous mechanism, in others on exacerbations of the lesion responsible; in the former it is usual to find that the dyspeptic disturbance disappears when the individual is removed from some enervating influence, as during a holiday.

The treatment of this type of gastric disorder is rapidly approaching the realm of rational therapeutics. The empirical use of alkalies in the treatment of dyspepsia generally has been attended with success in the majority of cases because they are of this type, and alkalies acting simply as neutralising agents counteract the excessive acidity of the stomach contents and so remove a potent factor in the production of the subjective discomfort. There is no evidence that the administration of alkalies before food exerts any stimulating effect on gastric secretion, as was formerly believed. A large draught of warm alkaline fluid may undoubtedly be beneficial as a cleansing agent in cases of catarrhal gastritis where the gastric mucosa is covered by a layer of mucus, and so get rid of a material which would utilise some of the digestive activity of the gastric juice secreted. On the other hand, alkalies administered during digestion act solely as neutralising agents, combining with the acid of the stomach contents, but effecting no alteration in the actual secretion of the gastric juice itself unless given in large quantities and for long periods, when a temporary depression of secretion has been produced. Since in reflex dyspepsia excessive secretion and excessively prolonged secretion of gastric juice are, in varying degrees, constant factors, the administration of alkalies during digestion is called for to neutralise the excessive acidity of the stomach contents. Of the various alkalies which may be employed the bicarbonate of soda, the carbonates of bismuth, magnesia and lime, and the oxide of magnesia, are the most useful. The action of the soluble bicarbonate of soda is rapid and ephemeral, that of the insoluble carbonates of the heavy metals is more prolonged. Bismuth possibly exerts some sedative action on the gastric mucosa; it is, moreover, constipating. Magnesia, on being converted into the chloride, exerts a laxative effect, accordingly varying combinations of the salts of bismuth and magnesia are efficient in neutralising the excessive acid of the stomach contents and in regulating the activity of the bowels.

The excessive secretory activity is associated with some perversion of the motility of the stomach, excessive peristalsis of the pyloric portion leading in many instances to rapid emptying of the stomach, and quite commonly to painful cramp-like spasms of the pyloric mechanism; the concentric tonic contraction of the body of the stomach—peristole—is also as a rule excessive, but with periods of relative

atony. As these perversions of motility are probably a direct effect of the excessive secretion, the neutralising effect of alkalies influences beneficially the disordered motility by removing the stimulus to its production. Belladonna exerts a direct inhibitory effect on the secretion of gastric juice as it does on the secretion of saliva, and further, it has the power of relaxing spasm of the gastric musculature; accordingly, the exhibition of this drug is indicated whenever there is excessive gastric activity; it is interesting to note that its action differs from that of alkalies in that it inhibits excessive reaction of the stomach to the stimulus to secretion, whereas alkalies merely neutralise the product of such excessive activity.

Neutral fats, as olive oil, oil of sweet almonds, fresh butter, cream, also exert an inhibitory effect on gastric secretion, and at the same time an inhibitory effect on gastric peristalsis, and so a meal taken within half an hour of the administration of half to one ounce of such a neutral fat on the fasting stomach passes into the duodenum more slowly, and partly by inhibition and partly by dilution, the acidity of the stomach contents is greatly reduced. It is evident, then, that in the alkalies, belladonna and neutral fats, we have the means by which the disordered functional activity of the stomach in reflex dyspepsia can be neutralised and counteracted, and by their rational use the subjective discomfort can be completely ameliorated, even the severe pain associated with pyloric and other forms of gastric spasm. The use of morphia, on the other hand, in such conditions is contra-indicated by the fact that it is a stimulant of gastric secretion, and while dulling the sensorium to the discomfort, exaggerates the local disorder from which that discomfort arises.

The drug treatment of reflex dyspepsia may be summarised as consisting in the administration of the alkaline salts of bismuth and magnesia in such quantity and combination as will neutralise the excessive acidity of the stomach contents and at the same time regulate the bowels, and of belladonna in doses of 5 min. of the tincture. These may be combined and given ten to fifteen minutes after food, the alkaline salts by their weight remaining in the stomach, and by their relatively slow action gradually neutralising the excess of acid as it is secreted; the belladonna also will have sufficient time in which to produce its inhibitory effect when most required, at the maximum phase of digestion.

To depress the reflex activity of the local nervous mechanism, a further indication in the treatment of this type of dyspepsia, the administration of bromides is called for, and either the potassium or sodium salt may be combined with the above. With this object also it is often essential that the individual should be removed from all enervating influences, as business and other worries, and in severe cases it is advisable to insist on a period of absolute rest in bed of at least a month.

The diet is equally important; there are certain foodstuffs which must be rigorously excluded by reason of their uselessly stimulating effect on gastric secretion—viz. coffee, strong tea, meat extracts, alcohol (unless very dilute), malt liquors, fried foods, especially starches cooked with fat, as pastry, fried bread, hot buttered toast, etc., stewed meats and highly seasoned foods. The amount of starchy food must be reduced, and what starch is allowed should be partially dextrinised, as in split toast, breakfast biscuits, rusks, crust.

Milk, cream, butter (cold), junket, eggs (raw or lightly cooked), custard, plainly cooked meats, steamed white fish—as plaice, sole, hake, birds boiled or plainly cooked in a casserole, grilled lean beef or mutton or plainly roast, purée of potato in small amount, of spinach or of turnip-tops, or French beans, two small cups of weak tea per day, provide the menu from which a suitable and varied diet may be selected.

Should the symptoms of dyspepsia persist with this régime, particularly should these be characterised by such manifestations of hyperacidity as heartburn, acid risings, etc., then the particular effect of the neutral fats may be utilised by the administration of olive oil or oil of sweet almonds in doses of half to one ounce half an hour before meals.

Organic Dyspepsia

Gastritis.—The indications for treatment are to remove the irritant responsible for the condition, and to aid in the restoration of the organ to the greatest possible anatomical and physiological integrity.

Acute Gastritis.—A condition of very diverse intensity, due to the local action of various irritant substances, calls for the immediate removal or neutralisation of the noxious substance and a variable period of physiological rest for the inflamed organ. The removal of the noxious substance is partly or wholly achieved by the vomiting which naturally occurs, and in such cases the only question to be decided is how far this shall be artificially modified. In any case seen in the early stage vomiting should be encouraged and its efficacy increased by the administration of warm water and irritation of the fauces if necessary, in children and strong adults the cleansing of the stomach may be initiated or accelerated by the simultaneous administration of some such emetic as zinc sulphate or vinum ipecacuanhæ, or by the passage of a soft stomach tube and lavage,

ut neither of these procedures should be emloyed where the inflammation is of the destrucive type produced by corrosive poisons, and in uch cases removal of the causal agent must be ttempted by dilution and neutralisation only.

The patient should then be placed in bed, ie extremities kept warm, and light fomentaons should be applied over the epigastrium t first with some such counter-irritant as urpentine or mustard until the skin is deeply ddened but not blistered. The mouth and eeth should be carefully cleansed with an lkaline antiseptic mouth-wash, and the patient hould be allowed to take cold water (iced) by ie mouth in teaspoonfuls every half hour. o attempt to administer any food should be nade for from twelve to thirty-six hours, ccording to the severity of the condition. Vhere the administration of water by the mouth s above induces retching, or where from the verity of the condition it is obvious that the omach must be kept absolutely at rest, ater should be administered by the rectum. fter a preliminary cleansing enema the atient should receive from ten to fifteen unces of normal saline at a temperature of 00° F., run slowly into the rectum from a innel and a rectal tube every four or six hours, r oftener should it be well retained and the ongue is at all tending to dryness. When ie condition is associated with marked restssness or when retching still continues, it is seful to add to every other saline, sodium romide in doses of from three to five grains o the ounce. Where the gastritis is associated ith severe enteritis and diarrhœa, severe epletion and collapse must be met by the xhibition of normal saline either subcutaneously r intravenously. When it appears that the dministration of water by the mouth causes o discomfort, it may be gradually replaced y whey, albumen water, and then milk, iluted with water, lime-water or soda-water, r citrated effervescent water as citoda, or ven weak tea without milk or sugar, which to nany patients is peculiarly refreshing. From iluted milk, the patient should be allowed such land foods as Benger's, Mellin's, Allenbury's, ago milk, rice milk, with rusks, and later junket, ustard, jellies, meat broths, and so gradually o a light diet of chicken and fish. Drugs may ot be required at all; on the other hand, it is enerally advisable to provide for thorough vacuation of the bowels by the early adninistration of ½ oz. castor oil with tincture f opium in 10 min. doses, or of calomel gr. every hour until the bowels act. When he administration of food is associated with iscomfort or a tendency to vomit, this may be net by the administration of either milk of nagnesia, with some carminative as spirits of chloroform or of a simple mixture of bismuth carbonate 10 gr., sodium bicarbonate 15 gr., sodium bromide 5 gr., in peppermint water, after food. Persistent retching, which occasionally occurs, can be relieved by cocaine in doses of ¼ gr. in a teaspoonful of water, given at intervals of an hour.

Collapse must be met by the administration of strychnine subcutaneously or brandy per rectum, in addition to the measures above indicated.

Chronic Gastritis.—Chronic gastric catarrh. These terms have been applied to various disorders of the stomach which have no relation in fact with chronic inflammation of the gastric mucosa. Genuine chronic gastritis in a degree to give rise to any recognisable subjective manifestations is a comparatively rare condition, and certainly very much less frequent than would appear from the frequency with which its existence is diagnosed. A conspicuous and characteristic feature of chronic gastritis is the presence of an abnormally large amount of mucus in the stomach contents, and occasionally it happens that this increased secretion of mucus is so considerable that the term *gastromyxorrhœa* has been applied to what is probably a variety of chronic gastritis. The secretory activity of the stomach in chronic gastritis shows considerable variations, in some there is hypersecretion, in others the secretion is normal, and again in others, and probably the majority, there is hyposecretion.

Treatment.—To avoid further irritation of the stomach the hygiene of the mouth, the method of mastication, and the diet must be carefully supervised. Carious and painful teeth, painful tooth-plates, pyorrhœa, must be looked for and put in order, faulty habits of mastication must be corrected. From the diet all irritating substances must be excluded, as alcohol, strong coffee and tea, spices and condiments, all highly seasoned and richly cooked foods, sweets, and the use of tobacco or other narcotic strictly regulated. The diet should consist of clear meat or vegetable soups, white fish steamed or boiled, plainly cooked meats, stewed tripe, chicken, grilled beef or mutton, green vegetable and potato in small amount in purée form, custard, junket, jellies, stewed fruits; split toast, thin stale bread, crust, rusks, butter, lightly cooked eggs, milk, plain or diluted with soda-water, lime-water, or citrated weak tea, and such alkaline waters as Evian, Vichy, Apollinaris, etc.

The excessive secretion of mucus must be dealt with either by systematic lavage or by large draughts of alkaline water. In severe cases the fasting stomach should be washed out each morning with an alkaline saline solution, as warm Vichy water or plain water,

to which a teaspoonful each of common salt and sodium bicarbonate have been added to each pint. If actual lavage is not employed, half a pint of hot Vichy water should be taken each morning.

All such cases derive considerable benefit from the routine treatment as carried out at various Continental spas, Homburg, Wiesbaden, Kissingen, in cases with hyposecretion; Carlsbad, Marienbad, Neuenahr, Vichy, Ems, etc., in cases with hypersecretion, where thorough lavage, either simple or in the form of a spray douche, is systematically carried out, and where diet and exercise can be more strictly supervised.

Of drugs, alkalies with bitters administered before meals are most useful. As sodium bicarbonate 15 gr., tincture of nux vomica 5 min., with infusion of gentian or condurango bark. In cases where there is manifest hyposecretion, this deficiency may be partially met by the administration of dilute hydrochloric acid after food, in combination with strychnine and quinine.

In many cases, especially where there is hypersecretion, there is an associated hepatic insufficiency, which appears to be benefited by small doses of Hyd. cum Cret. and Pulv. Rhei Co., each night, followed by a large draught of some alkaline saline aperient each morning.

Achylia Gastrica.—It is very probable that this condition of more or less complete deficiency of secretory activity depends upon chronic inflammatory changes in the gastric mucosa. Where the secretory activity of the stomach is so deficient as practically to exclude that organ from any digestive rôle, the obvious objectives of treatment must be to maintain the integrity of musculature of the stomach and to prevent stagnation. The diet should consist of such foods as remain in the stomach but a short time, and easily pass into the duodenum. Thoroughly cooked starchy foods, as rice, sago, tapioca, prepared oats, crust, breakfast biscuits, rusks, purée of potato, peas, beans, lentils, spinach, etc., may be allowed; of meats the most suitable are white fish, plaice, sole, hake, boiled or steamed, chicken, pigeon, pheasant and lamb, beef and veal, plainly cooked and minced, also tripe, cow-heel, calves'-feet and calves'-foot and meat jellies. Eggs in any form are to be excluded. Also the amount of fat as in milk, cream and butter should be somewhat curtailed. Of fluids, weak tea, aerated waters, and a little dilute claret may be allowed.

Any excessive secretion of mucus or any tendency to stagnation must be met by systematic lavage.

Of drugs the administration of dilute hydrochloric acid in doses of half a drachm well diluted after meals, together with strychnine and quinine, is most beneficial, by reason of their stimulating action on the gastric musculature, their antiseptic action, and the chemical action of the acid on the albumins. Hydrochloric acid may also be administered in a form with slower and more prolonged action as betain hydrochloride (acidol), which slowly decomposes in the stomach with the liberation of hydrochloric acid; the tablets in which form this substance is put up should be crushed before administration. Pepsin may also be given, along with hydrochloric acid or with acidol (acidol-pepsin).

Various preparations of the gastric juice of animals, as gasterine (dog), dyspeptine (pig), have been extensively tried, but with no very encouraging degree of success.

The general condition of the individual will also call for active treatment.

Gastric Ulcer.—The indications are to bring the stomach into such condition as will be most favourable to the complete resolution of the lesion, and to meet such incidental complications as may threaten the life of the individual. The situation of the lesion in the actively contractile wall of a viscus, the use of which is necessary to the nutrition of the individual, by precluding the possibility of visual inspection of the healing process, renders medical treatment peculiarly difficult and uncertain; and although gastric surgery has afforded abundant evidence that such lesions do soundly heal when the local conditions are made favourable, yet in the absence of actual inspection it is not possible to be certain in any case that the healing process has progressed sufficiently far as to warrant the individual safely assuming an ordinary mode of life. The disappearance of subjective and objective manifestations is no certain criterion, and even if the difficulty of maintaining any rigid system of treatment thereafter is overcome it is entirely a matter of speculation as to how long this should be maintained. The recurrence of manifestations some time after an apparently successful rest-cure is due in the majority of cases to the breaking down of an ulcer incompletely healed. The experiences of gastric surgery throw some light on the possibilities of the treatment of gastric ulcer by simple rest. After an operation involving section of the stomach wall it is common practice to allow food into the stomach on the second or third day, and a light but fairly complex diet by the end of the second week; from this it may be inferred that when a recent acute ulcer or erosion is so placed at rest that by contraction of the stomach wall its edges are brought into contact, it will heal rapidly and soundly; and further, that the factors which so obstinately militate against the sound healing of a chronic ulcer reside, not

in any conditions of the stomach as a whole or in any general condition of the individual, but in the ulcer itself, and, in fact, in the dense cicatricial base of the ulcer which admits only of such limited contraction that even with the stomach completely at rest the edges are far from being approximated. Under such conditions it is obvious that sound reparation of a large callous ulcer of the stomach must be a very prolonged process, and one which if incomplete must be fraught with the certainty of breaking down at an earlier or later period. It is thus evident that whilst the outlook for medical treatment is good in acute ulcer, it is but a temporary expedient in chronic ulcer, and any certainty of complete relief must be based on a much more prolonged régime than is usually practised.

From the therapeutic standpoint cases of ulcer of the stomach may be divided into—

1. Those in which perforation has occurred into the peritoneal cavity or into adhesions.

2. Those in which a manifest hæmorrhage has just occurred.

3. Those in which the manifestations do not include perforation, manifest hæmorrhage or mechanical disability of the stomach.

1. *Perforation.*—The existence of perforation is an absolute indication for immediate surgical intervention. Although there can be no doubt that minute leaking perforations do occur and heal with the formation of perigastric adhesions, yet in no circumstances, except where conceivably operation itself is the greater risk, should immediate surgical intervention be withheld.

2. *Hæmorrhage.*—Manifest hæmorrhage from the stomach or duodenum, whatever its presumable origin, must be met by rigidly confining the patient to bed, not allowing him to get up for micturition or defæcation, the head being kept low to obviate faintness. The mouth and teeth must be carefully cleansed with some alkaline antiseptic lotion, the colon cleared out with a large soap-and-water enema. An ice-bag slung from the frame of a bed-cradle should rest lightly on the epigastrium. The patient should then receive normal saline solution by the rectum, and nothing whatever, not even ice, by the mouth. The saline should be administered at a temperature of 100° F. by means of a soft rectal tube, inserted about six or eight inches into the rectum. Attached to the rectal tube by some two feet of rubber tubing should be a ten-ounce glass funnel into which the warm saline is poured, and which, after the flow into the bowel has been started, is adjusted to such a height as will allow of the flow to occur at the slowest possible rate; from ten to fifteen ounces should be administered at each operation, and to enable the flow to pass well into the bowel the patient's hips should be raised. The administration should be repeated every four, five or six hours, according to amount retained, endeavouring to get at least sixty ounces absorbed in the twenty-four hours.

As a rule the stomach, being at rest, contracts, and bleeding ceases spontaneously, the patient is comfortable and restful. This administration of saline should be continued for from forty-eight to seventy-two hours according to the severity of the hæmorrhage, when water in teaspoonful quantities may be tentatively administered by the mouth and increased as soon as it appears certain that it is well borne. During this period the mouth must be kept scrupulously clean and moist by the careful use of a suitable wash to obviate infection of the parotid glands through the ducts and consequent parotitis; as a further prophylactic measure, it is often advisable to induce slight salivary secretion by allowing the patient to chew a rubber teat or a piece of unflavoured chewing gum. A possible complication which must be watched for is the incidence of acid intoxication; the urine should be frequently examined for diacetic acid by the ferric chloride reaction and its appearance at once met by the addition of pure glucose (commercial glucose may contain arsenic in large quantities) in the normal saline in the proportion of from 3 to 5 per cent. Occasionally the patient is restless and alarmed, for which an initial dose of a quarter of a grain of morphia may be given subcutaneously or thirty grains of sodium bromide added to the first three or four salines. If in spite of this procedure the hæmorrhage recurs, then some styptic must be administered by the mouth; oil of turpentine I have found to be invariably successful; a tablespoonful is beaten into a fine emulsion with the white of an egg, and of this a teaspoonful is given every hour. The method sounds empirical, but it is one of the most certain, and the remedies are always to hand in practically every household. A method of administering turpentine which is not to be recommended consists in making the remedy more palatable by admixture with lemon-juice and sugar, since citric acid from its decoagulating action on the blood should be rigidly avoided. Of other styptics that may be employed, adrenalin chloride solution (1 in 1000) in doses of 10 to 20 min. in a tablespoonful of water may be repeated at intervals of three or four hours, or Liquor Ferri Perchloridi 30 min. in half an ounce of glycerine. Normal horse-serum also seems to exert a local styptic effect, and may be given in doses of 2 dr. in an ounce of water to be repeated in an hour if necessary.

If after a recurring hæmorrhage the rectal

salines are partly returned with decomposing blood, or if there is any marked intestinal distension from retention of such blood, the colon should again be washed out by a large soap-and-hot-water enema.

Rarely some difficulty in the administration of saline occurs from irritability of the rectum; this can generally be overcome by diminishing the amount at each operation and by the addition of 10 to 15 min. of Tinct. Opii to every second or third saline. Should it happen that absorption cannot take place sufficiently rapidly to meet or prevent urgent collapse, then an initial pint or two of normal saline should be given subcutaneously or intravenously.

During this period the patient receives nothing but saline solution, no attempt should be made to introduce food into the colon, the nutritive value of rectal feeding is very questionable, the nursing of the patient is unnecessarily complicated, the patient is rendered less comfortable, and is also exposed to toxæmia from absorption of products of putrefaction of the food introduced. Water alone is requisite and in sufficient quantity.

At the end of forty-eight or seventy-two hours half an ounce of sterilised water should be given by the mouth with a teaspoon, and if it produces no discomfort it should be repeated in half an hour, then freshly prepared albumin water is substituted, and two or three hours later milk diluted with an equal part of water, to which sodium citrate has been added in the proportion of two grains to the ounce. If at the end of six hours it is apparent that the half-hourly quantities of diluted milk are well borne, the amount may be rapidly increased, and at the same time the quantity of saline administered by the rectum correspondingly diminished. During the first twenty-four hours the patient should receive ten ounces of milk in which the whites of two eggs have been beaten up; it should be freshly prepared, kept on ice in a covered vessel and given hourly by means of a teaspoon; at the same time the patient may take gelatine jelly, allowing it to dissolve in the mouth.

On each succeeding day the amount of milk should be increased by two ounces, until the patient is taking thirty-six ounces in the twenty-four hours. On the second day the patient receives two whole eggs, and these are then increased one a day until the patient is taking six in the twenty-four hours; for the first five days the eggs are simply beaten up with the milk, on the sixth day one or two may be given in the form of custard. From the third day onwards the patient may also take an ounce of cream and an ounce of sugar, these being given partly along with the milk and egg and partly whipped into a foam with a little gelatine. On the seventh day the milk and eggs are given in part simply beaten up, in part as custard and in part as junket, also on this day the patient may be allowed a little sago, half an ounce boiled in milk, and a similar quantity of rusk grated in milk. On the eighth day the patient may be allowed an ounce of scraped raw meat divided into three doses, or two teaspoonfuls of somatose or plasmon. On the tenth day two ounces of tripe, raw or stewed in milk, or two ounces of scraped, lightly grilled steak, may be allowed. From the fourteenth day the patient is fed every four hours during the day, the diet being increased and varied by the addition of boiled calves' brains, minced boiled chicken, steamed plaice, thin split toast or rusk soaked in milk, and purée of potato and spinach in small quantity. Where whole milk gives rise to any discomfort, it may be modified by the addition of citrate of soda—two grains to the ounce—or by being treated with "Pegnin," a preparation which precipitates the casein in very fine curd; this so-called Pegnin-milk is pleasant to take, and is usually well tolerated when raw milk gives discomfort. The milk may also be diluted with lime-water or "Citoda," a citrated effervescent water. Or, lastly, it may be given in part as "malted milk."

Of drugs it is rarely necessary to administer any directed towards the gastric disorder; the bowels, which are ignored for the first four or five days, should then be maintained open by the daily administration of sufficient Carlsbad salt in eight ounces of hot water each morning.

From the fourteenth day onwards any anæmia should be dealt with by the soft mass of Blaud's pill in capsules, ten grains three times a day after food. When the patient experiences discomfort after food which cannot be overcome by varying the diet, some simple sedative as a mixture of bismuth carbonate and sodium bicarbonate with spirits of chloroform and peppermint water, may be given after food.

This method of dealing with ulcer from which recent manifest bleeding has occurred is one which experience has shown to be most efficient, but on the other hand certain authorities, led by Lenhartz, advocate a diet of which that begun in the schema on the third or fourth day is a modification, immediately following the hæmorrhage, and they report equally good results. It is well, however, to err on the side of conservatism in dealing with gastric hæmorrhage, and providing the patient receives a sufficient quantity of water, the starvation which absolute rest of the stomach entails is more than counterbalanced by the greater certainty of initial healing.

3. *Ulcers without Manifest Hæmorrhage.*—Rest and diet are the essential features of the treatment, drugs are subsidiary, and cannot be in any way regarded as a substitute. The patient should be confined to bed for at least four weeks in a recent ulcer, and for eight to ten weeks in ulcers of long standing. The mouth and teeth should be put into a thoroughly good hygienic condition. The colon should be evacuated by a soap-and-water enema. In cases of chronic ulcer where there is stagnation, the stomach should be carefully washed out with a soft velvet-eyed tube, twice or three times a week, using warm saline solution to which a drachm of sodium bicarbonate to the pint has been added, or warm Vichy water. It is also advisable to give the patient two or three test-breakfasts on consecutive mornings, consisting of ten ounces of weak tea without milk or sugar and four breakfast biscuits, the stomach contents being removed after the lapse of one hour, when by noting the amount of the contents withdrawn and the acid-values, free hydrochloric acid and total acidity, useful information can be obtained as to the secretory and motor activity of the stomach, which will provide a rational basis for the proper administration of neutralising and inhibitory remedies. It has been my experience that the nearer the ulcer is to the pylorus the greater is the acidity of the stomach contents and the greater the tendency to stagnation from pyloric spasm.

Moist heat should be continuously applied to the epigastrium for the first four weeks, either by simple fomentations, light poultices or a thermophor laid over a layer of moist flannel, care being taken that the skin does not become blistered or eroded. Such application, which is undoubtedly very soothing, appears to aid the healing process by inducing congestion, and at the same time serves a very important purpose in staying local spasm.

The diet must be so arranged that the patient receives the maximum nourishment with least bulk and in an unirritating and easily digestible form. Milk, cream, eggs, sugar, gelatine, constitute its basis, the quantities should be arranged according to the following schema—

	Day.						
	I.	II.	III.	IV.	V.	VI.	VII.
Milk .	10 oz.	15 oz.	20 oz.	25 oz.	30 oz.	35 oz.	40 oz.
Eggs .	2	3	4	5	6	7	8
Cream	½ oz.	½ oz.	1 oz.	1 oz.	1½ oz.	1½ oz.	2 oz.
Sugar	—	—	1 oz.	1 oz.	1 oz.	1 oz.	1½ oz.

At first the constituents are simply beaten up together, from the third day they may be administered in part as custard, junket and whipped and sweetened cream. The milk may be prepared with pegnin, or diluted with fresh barley-water, lime-water, or it may be citrated. For the first three days the patient is fed with a small spoon every hour, then to the end of the week every hour and a half. During the second week every two hours, the third week every three hours, and during the fourth every four hours. In the second week the patient also receives somatose, plasmon, sanatogen, valkasa, or other similar food proteins, and four eggs per day, one or two of which may be lightly poached, sago milk, split toast or rusk soaked in milk, stewed tripe, minced chicken or pigeon.

During the third week scraped underdone beef, thin stale bread in small quantity, butter. During the fourth week a small cup of weak tea, a little purée of potato, and various carbohydrate foods, as Benger's, Mellin's, Allenbury's, may be added to the daily dietary.

The bowels should be carefully regulated in recent ulcers after the third day, in chronic ulcers from the outset by the administration of some alkaline saline water, as ten ounces of warm Carlsbad water each morning on the fasting stomach.

Should the patient complain of thirst, it is better to give ten or twenty ounces of saline by the bowel than increase the amount of fluid by the mouth.

Medicinal Treatment.—Drugs are subsidiary to efficiently conducted rest and diet treatment, and in some cases may be entirely dispensed with. Where, however, there is considerable hyperacidity with associated discomfort or a tendency to spasm some time after food, alkalies, bismuth salts and belladonna by their antacid properties, are of great utility. A mixture of bismuth carbonate, magnesia, tincture of belladonna, or of bismuth carbonate and sodium bicarbonate, or sodium citrate and magnesia and tincture of belladonna, may be given ten minutes after food four times a day.

Various methods of drug treatment have from time to time been employed with the object of accelerating the healing process in the ulcer. Of these, treatment by bismuth salts is still practised, and in some cases with apparent success. In the usual practice of administering bismuth salts in an alkaline mixture after food, it is probable that the drug acts almost wholly as a neutralising agent; and in order that it may exert any protective or sedative action on the ulcer and thereby promote its healing, it is necessary that it be given in large doses and in the empty stomach. Fleiner, who systematised this method, advises the administration each morning after the fasting stomach has been washed out, of 150 to 300 gr. of bismuth subnitrate in 8 oz. of warm water by the stomach-tube, which is retained

in situ for that purpose; the tube is then partially withdrawn and the patient remains quietly in such position as it is believed will bring the drug in contact with the ulcer for five to ten minutes, the tube is then again pushed into the stomach and the excess of fluid withdrawn, and the tube removed. The patient continues in the same position for half an hour, when the first feeding is allowed. The method may be applied less rigorously by simply allowing the patient to drink the eight ounces of water in which the bismuth salt is suspended. In place of the subnitrate, bismuth carbonate, or a mixture of chalk and talc, or of bismuth carbonate and magnesia may be similarly employed, the subnitrate has the disadvantage of being an acid salt, whilst the carbonates may give rise to some distension by evolution of carbon dioxide. Further in place of simple water the salts may be suspended in warm Carlsbad water. It is not essential that the patient should assume any particular posture, as the drug is gradually disseminated over the whole mucosa and tends to collect in any depression that may be present, accordingly it is sufficient for the patient to lie quietly for half an hour before taking any food by the mouth.

Silver nitrate was formerly recommended as a remedy in gastric ulcer, one drachm of a 1 in 600 solution being given three times a day on the empty stomach, and gradually increased to one drachm of a 1 in 300 solution. In pill form it should not be employed. In several cases I have tried the effect of washing out the stomach every other morning with a 1 in 2000 solution for five minutes, finally running off the whole of the solution and washing out with normal saline; the results were certainly an improvement on those previously obtained in these cases by the bismuth method, and the method is worthy of further trial in suitable cases of chronic ulcer.

More recently normal horse-serum has been advocated as an antilytic in gastric and duodenal ulcers; the serum must be fresh, and is administered by the mouth immediately after food in doses of two drachms in half an ounce of water three or four times a day. I have, however, not been able to determine any particular benefit from its employment.

Of individual symptoms, pain and vomiting may by their predominance call for special treatment. The pain in gastric ulcer is in the majority of cases due to localised muscular spasm, occasionally to peritoneal irritation; morphia is contra-indicated in such cases owing to its stimulating action on gastric secretion, whereby the local condition is made worse while only the receptive centres are dulled; on the other hand, alkalies and belladonna with the local application of heat are efficient. In cases with persistent vomiting, should this manifestation fail to subside with variation of the feeding and the administration of bismuth salts in combination with bromides and belladonna, cocaine in doses of quarter of a grain in a teaspoonful of water ten minutes before food should be tried, and if this fails rectal salines employed exclusively for twenty-four or more hours.

Indications for Surgical Treatment.—Briefly, whenever the functional activity of the stomach is mechanically interfered with as by stenosis of the pylorus or body of the stomach (hourglass) or by perigastric adhesions; when in chronic ulcer the symptoms recur after a thorough rest-cure, and are of a nature that even for bare tolerance the individual is compelled to lead such a restricted mode of life as interferes with his temporal and mental welfare; when the life of the individual appears to be threatened by recurring hæmorrhage, and when there is any reason to suspect the possibility of the supervention of malignant disease, then surgical methods of treatment are indicated.

Cancer of the Stomach.—The medical treatment of cancer of the stomach is wholly palliative. The diet should be composed of fluid and soft foods, stimulating and nutritious, and any predilections of the patient should be met as far as possible. Beef-tea, meat extracts, with the addition of milk or eggs, coffee and milk, tea and milk, rusks, split toast, or crust soaked in milk, stewed tripe, minced chicken, scraped meat, lightly cooked eggs, custard, junket, and such carbohydrate foods as Benger's, Mellin's, Allenbury's, etc.

Of drugs, dilute hydrochloric acid in doses of 20 to 30 min., along with strychnine and infusion of condurango, should be given after food to assist the defective gastric activity. In some cases, however, it will be found that acids increase the discomfort produced by food, and in such a bismuth and soda or bismuth and magnesia mixture containing tincture of belladonna and tincture of Nux Vomica is more efficient.

Stenoses of the Stomach.—Permanent stenosis of the pylorus or of the body of the stomach (hour-glass stomach) is at once an indication for operative treatment, and only when this is not available is medical treatment called for. The indications are to maintain the motor activity of the stomach, to prevent any superadded spasm, to provide a diet which shall leave the stomach rapidly, to prevent stagnation, and, as but little water is directly absorbed from the stomach itself, to provide for this requirement of the individual in greater or less part by rectal salines.

Where the secretory activity of the stomach is normal or excessive as in cicatricial stenosis, the diet should consist of easily digestible proteins, of fats and a minimum quantity of partially dextrinised starchy food. Milk, cream, butter, custard, junket, underdone meat, steamed white fish, pigeon and chicken cooked in casseroles, rusks, split toast, bread crust, etc. Where, as in malignant disease, the secretion is defective, it is advisable to withhold fats—cream and butter—and to give stimulating foods as beef-tea, meat-juice, meat jellies, meat extracts, and such peptonised foods as milk, gruel, custard, Benger's food, malt rusks. The stomach should be washed out with an alkaline saline solution containing a drachm each of sodium bicarbonate and sodium chloride to the pint of warm water, or warm Vichy water every morning or every other morning according to the degree of stagnation and hypersecretion.

Of drugs, where the secretion is excessive, alkalies and belladonna after food are indicated, and where there is evidence of super-added spasm the meals should be preceded by a tablespoonful of olive oil or oil of sweet almonds; but where the secretion is deficient, dilute hydrochloric acid and strychnine also after food.

The treatment of the hypertrophic pyloric stenosis of infants should be conducted on the lines above indicated, the diet, however, being arranged to suit the age of the child.

Gastroptosis.—It is very probable that simple downward displacement of the stomach does not in itself give rise to any subjective manifestations of gastric disability, and that only with the supervention of atony in the body, (deficient peristole) does it become associated with subjective symptoms. Accordingly the treatment is that already described under *Atonic Dyspepsia*—that is, systematic abdominal massage, dieting and later some form of mechanical abdominal support, such as a simple well-fitting belt to support the lower abdomen, or a firm oval pad across the hypogastrium held in position by steel springs from dorsal pads much like the springs of a truss (Curtis), or the pneumatic belt of Charnaux. Support may be arranged by broad strips of strapping; this has the advantage that it can be applied to give support where and how it is needed, that it is more fixed; on the other hand, it is apt to be irritating and requires frequent renewal.

Nervous Disorders of the Stomach.—It would be perhaps more correct to describe the disorders included under this heading as nervous disorders with gastric manifestations. Aerophagia, or air-swallowing, rumination or merycism, and nervous vomiting. The treatment in all cases has to be directed to the general condition and to the nervous instability, primarily and chiefly, careful supervision, correction of bad habits (sexual perversion is not infrequently an important factor), moral suasion, isolation, a rigid course of Weir-Mitchell treatment, and of drugs, bromides in combination with large doses of valerian and of asafœtida. F. C. M.

TREATMENT OF DISEASES OF THE INTESTINES

DUODENAL ULCER

The treatment of duodenal ulcer does not differ from that of gastric ulcer (*q.v.*). But the tendency for a healed ulcer to break open again and for new ulcers to develop is greater, and consequently the after-treatment requires special consideration. It is not difficult to cause a duodenal ulcer to heal by suitable treatment in bed, but the unknown essential cause which led to the ulceration remains, and is probably still present for many years.

Special precautions are therefore required to prevent a recurrence, and it is generally advisable to give written instructions, which the patient should follow for some years or even permanently.

The teeth should of course be put into thoroughly good condition at the beginning of treatment, but the patient should in addition be instructed to have them overhauled at least twice a year, so that the slightest tendency to pyorrhœa alveolaris can be kept in check. He should eat slowly and masticate thoroughly; it is a good plan to give him solid food during the last fortnight of his treatment in bed instead of minced and pounded food, so that he may get into the habit of eating slowly, for when the habit is once acquired, it is easy to continue in the same way. It should be impressed upon busy men that it is better to eat nothing at all than to bolt unchewed food. When there is no time to sit down to a proper meal a glass of milk should be drunk or some chocolate slowly eaten.

Barclay and the author have shown with the X-rays that the stomach in patients with duodenal ulcer empties itself with excessive rapidity, in contrast with what occurs in gastric ulcer, when the evacuation is at the normal rate or delayed. The secretion of gastric juice continues, however, after the stomach is empty; it is the irritation of the duodenal mucous membrane by the undiluted and uncombined acid which causes new ulcers to form and scars of old ulcers to break down. The patient should therefore drink a glass of milk or eat a biscuit about two and a half hours after break-

fast and last thing at night in addition to taking his breakfast, lunch, tea and dinner, the time of which should be so arranged that not more than three hours elapse without taking food. The patient should have some food at his bedside to take at once if he wakes during the night.

He should avoid the pips and skins of both raw and cooked fruit, and pickles, salads and all cooked vegetables, such as celery, which cannot be chewed to a semi-fluid consistence; green vegetables are best given as purées with butter. No aerated drinks and no alcohol should be allowed, except a little very diluted whisky with meals for those who feel the need of it. Vinegar and acid fruit should be avoided, and salt fish and meat, high game, curry and made-up dishes should be prohibited.

Individuals with the duodenal ulcer diathesis frequently suffer from cold extremities, and attacks often begin within a few hours of exposure to cold. It is therefore most important to warn patients to keep their hands and feet warm; they should have a hot foot-bath before going to bed, and use bed-socks or a hot-water bottle if the feet are cold at night. They should change their clothes at once if wet through, and if they feel chilled they should have a hot bath and go to bed without delay. When possible they should live in a warm and equable climate and avoid the English winter.

The bowels should be kept regular, and this can be done most conveniently by means of oxide of magnesia, which should be given after each meal and with the intermediate feeds, as it then helps to neutralise the excessive acidity of the gastric contents. The most convenient way to take it is in a fluid preparation containing 5 gr. of magnesia to the drachm, from ½ dr. to ½ oz. being required as a dose.

If the patient is thin, he should take a tablespoonful of olive oil before each meal, as it is not only a very useful food but it diminishes the secretion of gastric juice. Liquid paraffin has neither of these actions, but if the magnesia does not suit or is insufficient to control the constipation, a tablespoonful may be given after one or more meals.

In severe cases it is advisable for a time to give 5 min. of tincture of belladonna half an hour before meals to reduce the acidity; this should be given again for a few weeks if there is a temporary return of symptoms, however slight.

Patients should be warned of the danger of recurrence, and should be told to go to bed on a milk-and-egg diet at the first suspicion of a return of symptoms. If they do this, treatment for twenty-four hours is often sufficient to ward off an attack. If, on the other hand, they wait until the symptoms become fully developed, a prolonged stay in bed will be required.

An operation should be advised under the following conditions—

1. At the earliest moment after a perforation.
2. For pyloric obstruction, even if this is so slight that it is only recognisable with the X-rays, no obstructive symptoms being yet present.
3. In the very rare cases in which the ordinary treatment with rest, diet and drugs does not relieve the symptoms.
4. When the symptoms recur after one or more courses of thorough medical treatment; the number of such courses which may be tried depends upon such circumstances as the age, social position, occupation and place of residence of the patient; thus the older a patient, the better his social position, the less strenuous his occupation and the less important occasional absences from business, and the warmer and more equable the climate the less urgent is the necessity for operation.
5. When more than one severe hæmorrhage has occurred or when occult blood remains in the stools after a severe hæmorrhage in spite of treatment.
6. When there is evidence of chronic appendicitis, as recurrences are likely to occur unless the appendix is removed. Appendicectomy without gastroenterostomy is probably sufficient in such cases. A. F. H.

Surgical Treatment of Duodenal Ulcer

Both clinically and in the text-books the individuality of duodenal ulcers has been overshadowed by the greater frequency of the neighbouring gastric ulcers. Our knowledge has been progressing steadily for years, but the greatest advance, with reference to the subject under discussion, has been in our cognisance of the interrelation of the different parts of the alimentary tract. The information was first gained from skiagraphic examinations made in search of the factors which cause intestinal stasis. It has been learned that when the ileum contracts the unhealthy duodenum writhes. Further, we have begun to believe that the comparatively late onset of symptoms in the subjects of duodenal ulcer, *e. g.* pain two hours after food, is due to this duodenal writhing. Hence, when the presence of a duodenal ulcer is ascertained, the physician in charge must not rest satisfied, but look for factors producing stasis in the ileocæcal region. For unless these ileocæcal factors are removed, when present, treatment of the duodenal ulcer will not be satisfactory. The relationship between the duodenum and the cæcal end of the ileum is close, but not fully understood at present. But it suggests an obvious reason for the success of appendicectomy, in suitable cases,

for appendix dyspepsia. It certainly constitutes the very first principle of the successful treatment of a duodenal ulcer.

It is agreed that all perforations of a duodenal ulcer have a solely surgical treatment. But it is necessary to call in the aid of surgery in some instances when the ulcer has not perforated. These must be briefly referred to for us to understand the principles of the surgical treatment of duodenal ulcers.

Pain.—This may be so severe or disabling as to call for the performance of a gastro-enterostomy plus occlusion of the pylorus.

Hæmorrhage.—This may demand similar surgical measures. But hæmorrhage from the main trunks of the pancreatico-duodenal vessels will not be stopped by any measure short of ligature of that vessel. It might be likened to the suggestion of doing a gastro-enterostomy alone for a perforation.

A dilated stomach, tetany, hypersecretion in the stomach, and perhaps *cholecystitis* and *pancreatitis,* which suggest an infective condition of the duodenum, are non-perforative conditions of a duodenal ulcer which demand operation. As years bring more knowledge to us it is seen that the medical treatment of duodenal ulcers is more and more relegated to the period before a diagnosis is made. As soon as the diagnosis is certain, surgical treatment is required.

In such treatment an anterior or a posterior gastro-enterostomy seems equally effective, provided the pylorus is narrowed or occluded by disease, stitching, band or ligature.

The perforation of an ulcer may be acute or chronic, intra- or extra-peritoneal. The acute are almost always intraperitoneal and most amenable to treatment. For success to be attained it is necessary that the diagnosis should be made quickly. Every few hours after the perforation make a great difference to the mortality from the condition. Surgical intervention alone can snatch the patient from death. The surgical procedures consist of—

1. An incision between the umbilicus and the pubes, to exclude appendicitis, salpingitis, etc., and enable the surgeon to cleanse, and perhaps, drain the flanks, iliac fossæ and pelvis.
2. A second incision is made through the medial part of the right rectus, above the umbilicus.
3. The perforated ulcer is then found, sutured, excised or tamponnaded according to the circumstances of the case and the predilections of the surgeon.
4. The peritoneal cavity is cleansed, by "sponging," not lavage, which would disperse the infection, and either closed or drained. Personally I feel sure that to drain is safer than not to drain.

A primary gastro-enterostomy is rarely needed; one, later and secondary, may be, particularly if the ulcer has been excised or successfully sutured.

Chronic perforations form localised collections of pus which require incision and drainage. Too often they are followed by the formation of a duodenal fistula requiring gastro-enterostomy plus pyloric occlusion.

In extraperitoneal perforations pain is usually the most marked feature. Gas escapes through the ulcer into the subperitoneal tissue so that the omentum, for instance, may be so "blown-up" as to look like lung. These extraperitoneal ulcers, if acute, are difficult to find, and are very fatal.

A chronic extraperitoneal perforation demands usually a gastro-enterostomy with pyloric occlusion. E. M. C.

DIARRHŒA

Acute Diarrhœa

Acute diarrhœa is always due to abnormal irritation of the colon, generally owing to the consumption of decomposing food or to an intestinal infection which results in the abnormal decomposition in the bowel of sound food. The patient should be kept warm in bed until all symptoms have disappeared. If he is seen within twelve hours of the onset, he should be given from $\frac{1}{2}$ to 1 oz. of castor oil to clear the irritant material out of the small as well as the large intestine, unless the diarrhœa is so severe that it appears probable that this has already occurred. When the stomach has been irritated at the same time it may be necessary to wash it out. No food should be given for twenty-four hours or even longer in severe cases, but the patient may drink as much water as he likes. Arrowroot made with water to which sugar can be added should then be given, but nothing else until the diarrhœa has ceased. Milk, junket, bread and butter and milk puddings should then be given and a gradual return should be made to an ordinary diet, the speed with which this is done depending on the severity of the case. Carbohydrates should be added to the diet before proteins, and meat should be given last of all, but after a severe attack the patient should avoid raw vegetables in the form of salads or pickles and excess of fruit for some weeks, as otherwise a relapse is likely to occur.

The only drug which is of real use in acute diarrhœa is opium and its alkaloids. If the diarrhœa shows no signs of abating after twenty-four hours some preparation of opium, morphia or codeine, should be given, the dose being regulated according to the severity of the diarrhœa and the general condition of the patient.

Chronic Diarrhœa

The successful treatment of chronic diarrhœa depends upon the recognition of its cause. Most frequently it is a result of excessive stimulation of the intestinal movements, but in some cases it is a result of over-excitability of the neuro-muscular mechanism which controls the movements. Those cases which are secondary to organic disease of the intestine, such as colitis and cancer, are separately considered.

1. *Excessive Stimulation of the Intestinal Movements.*—The treatment of this form of diarrhœa consists primarily in the removal of the cause. The question of diet first requires investigation. In some cases excess of vegetable food has been consumed, and a diet containing no vegetables, except potatoes, and no fruit, whether raw, cooked or as jam, will result in the disappearance of the diarrhœa. More commonly the diarrhœa is due to excessive fermentation of carbohydrates or excessive putrefaction of proteins. The character of the stool and especially the smell and reaction of a specimen after incubation for twenty-four hours indicate whether either of these conditions is present, excess of gas being produced in both cases; it is odourless in fermentative diarrhœa, but ammoniacal in putrefactive diarrhœa, the reaction of the stool being acid in the former and alkaline in the latter instead of almost neutral. In *fermentative diarrhœa* starch should at first be completely excluded from the diet, but sugar, malt extract and milk are allowed. When the diarrhœa has stopped, cellulose-free starch, such as arrowroot, may be given, but no potatoes, white bread or rice for several weeks, and no vegetables containing a greater quantity of cellulose until still later.

A lacto-vegetarian diet is most suitable for *putrefactive diarrhœa.* Some of the milk may be replaced by sour milk. No meat should be allowed until the diarrhœa has ceased for a fortnight.

A rare but important form of chronic diarrhœa is that which occurs in achylia gastrica, the absence of gastric juice allowing the passage of an abnormal quantity of organisms and of undigested meat into the intestines, with the result that excessive putrefaction is likely to occur. This *gastrogenous diarrhœa* rapidly improves on the diet already described as suitable for putrefactive diarrhœa, but a relapse is certain to follow a return to an ordinary diet unless hydrochloric acid is given. The patient should take at least 15 min. of the dilute acid during and again after each meal for the rest of his life, unless the achylia is due to chronic gastritis, in which case the normal secretion of gastric juice may eventually return. The acid may be added to the water the patient drinks during his meals; if a little albumen and sugar are added it is not unpleasant and most patients eventually become accustomed to it.

The chronic diarrhœa which sometimes occurs in Graves's disease, uræmia and septicæmia disappears as the primary condition improves. As symptomatic treatment, the subcutaneous injection of 2 min. of adrenalin chloride three or four times a day is often very efficacious in the diarrhœa of *Graves's disease,* whilst that of *uræmia* may cease on reducing the quantity of protein in the diet.

2. *Nervous Diarrhœa.*—Under normal conditions the entry of food into the empty stomach gives rise to a gastrocolic reflex, which is the chief stimulus to the movements of the colon. In most individuals this is only followed by defæcation after breakfast, as the pelvic colon is then full and the sudden passage of fæces from it into the rectum gives rise to the call to defæcation. In individuals with an abnormally excitable nervous system the gastrocolic reflex may cause a further quantity of fæces to reach the rectum after each meal. Such individuals generally pass a formed stool immediately after breakfast; this is often followed by one or more loose stools, additional ones being also passed after lunch and dinner, especially if the patient is particularly anxious that his bowels should not open, but is frightened that they will do so. Such cases are hardly influenced by diet, but drugs which diminish the activity of the gastrocolic reflex, either peripherally or centrally, are very effective. A mixture containing 5 gr. potassium bromide and 5 min. tincture of belladonna taken half an hour before meals is generally all that is required in mild cases; in severer cases a small dose of codeine should be added. The exact dose of each drug requires modifying to suit each patient, as different individuals react very differently to these drugs, especially to belladonna. Arsenic has been recommended for these cases, but I have rarely found it of much use, and in some cases it has actually aggravated the condition. When the diarrhœa has been completely controlled the dose of the drugs should be gradually reduced and their use can finally often be discontinued, at first before lunch and dinner and finally before breakfast, without any return of symptoms. In most cases it is still advisable to allow the patient to have the medicine or a pill containing belladonna and codeine always with him, so that he can take a dose before going to a dinner party or on any other occasion when he fears that he will have diarrhœa. He soon learns to trust so thoroughly in his pill that it probably acts more by suggestion than in any other way, and the dose can accordingly be progressively reduced until it is infinitesimal.

In many cases of diarrhœa due to other causes the bowels act most frequently after meals. In such cases the treatment just described is often of use in conjunction with that required for the primary condition.

A. F. H.

CONSTIPATION

For the rational treatment of constipation it is necessary to distinguish between the three great classes of cases: (1) that in which the passage through the colon is delayed, whilst defæcation is normal—colonic constipation; (2) that in which there is no delay in the arrival of fæces in the pelvic colon, but their final excretion is not adequately performed—pelvirectal constipation or dyschezia; and (3) that in which the quantity of fæces found is insufficient to produce an adequate stimulus to the intestinal movements and to defæcation.

Hygiene of the Bowels.—In no circumstances should the patient fail to make an effort to open his bowels after breakfast, even if he feels no desire to do so, and a call to defæcation felt at any other hour in the day should be obeyed at once at whatever inconvenient time it may occur. Sufficient time should always be spent over the act of defæcation, and it may be advisable to pay two visits to the closet at short intervals. In order to prevent the temptation to hurry over defæcation the closet should be clean, devoid of smell and properly warmed in winter. In dyschezia a footstool nine inches lower than the seat should be provided, so that the crouching position may be assumed during defæcation.

Diet.—It is important to see that sufficient food is taken, as constipation is often as much due to its insufficient quantity as to its unsuitable quality. The diet should contain an increased proportion of fat and of vegetable foods, especially those which contain much cellulose, organic acids and sugar. Thus green vegetables or salads should be taken twice a day, and fruit, whether fresh or dried, raw or cooked, at breakfast, lunch and dinner. In addition to that taken with meals, a glass of cold water should be drunk before breakfast, another just before retiring to bed and perhaps a third half an hour before dinner.

Drugs.—The majority of cases of constipation can be cured without drugs, if proper treatment is instituted at a sufficiently early stage. In dyschezia purgatives are either absolutely useless, or they only have an effect when fluid stools are produced, a considerable quantity of fluid and nutritive material being thereby wasted. In curable diseases, such as chlorosis and neurasthenia, and in incurable diseases, such as Bright's disease, diabetes and insanity, all of which are aggravated by constipation, purgatives should be regularly given. They are also useful for making the stools soft when defæcation is painful as a result of inflamed hæmorrhoids or anal ulcer and in diseases of the pelvic organs, and when straining at stool is accompanied by danger, as in patients with cardiac degeneration and in those liable to cerebral hæmorrhage on account of high blood pressure. In cases of constipation due to other causes, in which non-medical treatment proves insufficient, purgatives must also be used, but an effort should be made to dispense with drugs at the earliest possible moment. The stool produced by an aperient should be normal in size and consistence, and should not deprive the body of any water or nutritive material which ought to be absorbed. The dose should be so regulated that one stool is passed every day and the desire to defæcate is felt immediately after breakfast. The aperient should cause no pain or discomfort, and should not irritate the intestinal mucous membrane sufficiently to produce any inflammatory change. If it is probable that the purgative will be required permanently, one such as aloes, cascara or senna should be chosen, which is likely to maintain its good effect without any increase in the dose being required.

In constipation due to a greedy colon the bulk of the fæces must be increased by the administration of some unirritating substance, such as liquid paraffin or agar-agar, which passes through the intestines without undergoing decomposition or absorption. Liquid paraffin is particularly valuable when the fæces are hard and dry; it is therefore useful in other forms of constipation besides that due to a greedy colon, as, for example, in diabetes. In dyschezia also the soft stools which result from its use are expelled with less difficulty than ordinary fæces. From 1 dr. to ½ oz. should be taken with meals two or three times a day.

Enemata.—The majority of cases of moderately severe constipation are more or less cumulative, excess of fæces being always present in the large intestines. It is therefore necessary that the colon should be completely evacuated before other methods of treatment are adopted. It is generally possible to empty the bowels completely by means of a dose of castor oil, followed, if necessary, by a saline purge. In severe cases, however, it is necessary to remove the accumulation of fæces from the large intestine by enemata before other treatment is attempted, and in rare instances the rectum can only be emptied by means of the finger.

It is essential in treating dyschezia to keep the rectum and pelvic colon empty so that they may in time regain their normal tone and contractile power. This can only be accomplished by the regular use of enemata of water

or glycerine. The bulk of the water enemata and the strength of the glycerine enemata should be gradually reduced. As a rule the tone and contractile power slowly return and a cure finally results.

Hydrotherapy.—A cold bath or a cold douche after a hot bath is a very valuable addition to the series of stimuli which lead to the morning evacuation. The spasm in spastic constipation is often benefited by a hot bath, and when constipation is due to some painful pelvic condition, the latter and the associated spasm of the sphincter ani may be relieved by the use of a hot sitz-bath.

Rest, Exercise and Massage.—In neurasthenic constipation, and whenever the patient is under-nourished, rest in bed for some weeks is very beneficial, and if sufficient food is taken, the bowels may act without the aid of drugs or enemata. Regular exercise in the open air is one of the most important means of preventing constipation, especially in individuals who follow a sedentary occupation. It increases the appetite, diverts the mind, strengthens the voluntary muscles of defæcation and stimulates the intestinal movements. When any of the voluntary muscles of defæcation are weak, considerable benefit can be gained by the performance of Swedish exercises every morning and evening. Whenever constipation is due to want of activity of the intestinal musculature, the condition of the latter may be improved by deep abdominal massage, the efficiency of which is greatly increased if the masseuse gives the first treatment under the X-ray screen after a barium meal so that she can see exactly what manipulations are required to act upon the colon, and to restore a dropped colon to the normal position.

Dyschezia is often associated with visceroptosis, both being due to weakness of the abdominal muscles. In such cases a proper support is of great value.

Spa Treatment.—Many patients, who are unwilling to undergo any systematic treatment for constipation at home, readily agree to devote a few weeks in the year to a "cure" in some popular health resort. The removal from business and household worries, daily exercise in the open air, regular hours and the change from rich food to a suitable diet are of much more importance than the drinking of waters, which could be done equally well at home, if they were really needed. In most of the resorts which are regarded as suitable for constipated patients, excellent arrangements are at hand for hydrotherapy, massage and electrical treatment, and better results are obtained from intestinal lavage in such places as Harrogate, Llandrindod Wells, Plombières and Châtel-Guyon than at home.

Operative Treatment.—When constipation is the result of definite organic obstruction of the intestine, surgical treatment is clearly indicated. Unfortunately several operations have been recommended in the last ten years for the relief of constipation in the absence of this clear indication, and consequently the results hitherto obtained have only been satisfactory in a comparatively small proportion of cases. Surgical treatment should not be recommended for chronic constipation unless all of the following conditions are fulfilled :—

1. Prolonged medical treatment has failed to give relief. By "relief" I do not mean cure, as many patients continue to be completely relieved of their constipation and the symptoms to which it has given rise so long as they continue medical treatment.

2. An accurate diagnosis is essential. The part of the bowel in which stasis is present must be accurately determined as well as the presence or absence of dilatation, narrowing or adhesions; in the case of the latter an attempt must be made to ascertain how far, if at all, they interfere with the normal intestinal functions. An X-ray examination of the stomach and intestines should therefore always be carried out, and the rectum and pelvic colon should be examined with the sigmoidoscope as well as with the finger. The history should be taken with great care and the patient's other organs thoroughly examined in order to determine whether the intestinal condition is primary and the cause of all the symptoms.

3. The operation should be chosen to suit the particular condition found. It is clearly absurd to recommend appendicostomy, ileo-sigmoidostomy or colectomy as the routine treatment for a condition which has such a manifold pathology as constipation. In some of the rare cases in which surgery is required, one or other of these operations may be indicated, but in others an operation devised to short-circuit or excise the affected part only and not the whole colon should be performed.

4. The dangers and possible unpleasant sequels of the operation should be weighed against the severity of the symptoms, for which it is proposed to operate. Appendicostomy is almost free from danger to life, but in rare instances unpleasant local complications have occurred. All the other operations, which have been recommended for constipation, have a definite danger. The mortality of simple short-circuiting operations is small, but it is greatly increased if adhesions are divided at the same time, and the mortality of partial and, to a still greater extent, that of complete colectomy is high, even in the most skilful hands. It is clear, therefore, that such operations should not be lightly recommended, and that they should only be performed for symptoms which are really

severe enough to interfere considerably with the enjoyment of life or with the performance of the professional or other duties of the patient.

A. F. H.

SURGICAL PRINCIPLES IN THE TREATMENT OF APPENDICITIS

At the outset it should be made clear that the present article is not concerned with the treatment of acute perforative or "septic" appendicitis with early symptoms of general peritonitis. I have elsewhere endeavoured to point out that where there is the slightest doubt in such cases, early and immediate operation is imperative. In this article we are concerned only with what I may term (1) *Acute Appendicitis* in its early stages, (2) *Chronic Appendicitis.*

Under *acute appendicitis* I class those cases where, in addition to the localising symptoms of appendicitis—pain, tenderness, vomiting—there is evidence of septic absorption as shown by fever, increased pulse rate, leucocytosis.

Under *chronic appendicitis* those cases are considered in which there is evidence of septic absorption, and where the symptoms of appendicitis may be doubtful, and perhaps only localised after prolonged and careful examination has excluded other conditions; or even those cases where the only "evidences" of appendicitis may be symptoms of colitis, dyspepsia, or even chronic constipation. These chronic cases show a variety of macroscopic conditions of the appendix, kinking, thickening of one part, stenosis of the proximal part, adhesions, etc.; microscopically, varying degrees of destruction of the mucous membrane, round-cell infiltration of the submucous and muscular coats, concretions and contents of various degrees of septicity are found.

In *acute appendicitis* the treatment should be unhesitating; in all such cases I believe that immediate removal should be insisted on. Should the patient refuse when the position has been fairly and carefully explained, the responsibility is no longer the doctor's, and the usual palliative measures should be adopted—absolute rest in bed, fluid diet, ice-bags to the abdomen, small doses of belladonna, and above all a careful watch on the pulse-rate and temperature. Small enemata may be given to clear the lower part of the large intestine, but no active purgative should be given by the mouth.

In advocating immediate surgical operation on all cases of appendicitis which come under the class I have taken as *acute*, I am well aware that I may be addressing myself to some readers who will continue to regard it as merely the promptings of a surgical mind, "Oh," they will still continue to say, "many cases get perfectly well by careful dieting without operation." It may be so, yet I cannot help wondering whether such cases were ever really *acute* appendicitis. To attempt to convert such minds is perfectly idle; like that voracious bird the ostrich—who, by the way, has not got an appendix—they deliberately push their heads into the sand and shut their eyes to the tragedies that are *always* around us; a fatal case of appendicitis is to them as inevitable (and as infrequent) as is the death of an "air-man." Such opinions are now fortunately those of only a small and decreasing minority; the vast majority of practitioners, physicians, and surgeons are *now* in agreement.

The reasons for this opinion are shortly these—

1. The patient's safety; for the risks of an early operation are very small indeed, while it is well known that the symptoms from hour to hour cannot be relied on—pulse rate, pain, muscular rigidity, all may be deceptive. It is impossible to diagnose the absence of pus, and in many a patient for some time after actual perforation appears to be better.
2. If pus *has* formed the sooner it is drained the better. Moreover, the chance of removing the appendix before an abscess cavity has formed is much greater, while drainage in a doubtful case relieves pain and distension, and can do no harm.
3. If pus is not present, despite our diagnosis, the patient is taking no risk and will recover more rapidly than if he is left to face unnecessary risks and submit after convalescence to an operation "à froid." My own experience is that although there is often considerable difficulty in these early operations there is no increased risk to the patient. The essentials of success are: (1) patience and great gentleness on the part of the surgeon; (2) haulage and stimulation of the intestines after the methods of the sausage-maker are not to be recommended; (3) use iodine catgut throughout; (4) a long external incision; (5) muscle splitting and carrying the incision between the muscle fibres if necessary down the posterior wall of the sheath of the rectus (to get more room I would advocate an incision in the linea semilunaris, despite other opinions, in all cases where pus is believed to be present); (6 protection of the whole abdominal wall after the peritoneum has been opened by rubber tissue. After the operation the patient is kept sitting up, and castor-oil is given within thirty-six hours of the operation, and the treatment continued if necessary as in that for ileus of septic peritonitis.

Treatment of Chronic Appendicitis.—Here the practitioner should be assured that if the case *is* really one of chronic appendicitis it is most improbable that any measures short of removal

of the appendix can be of avail. It will be conceded that acute appendicitis is probably the result of a flare-up of chronic appendicitis, and, most usually therefore, if we are sure of our diagnosis, the patient's safest course is to have the appendix removed at a time when there is practically no risk at all in the operation. Moreover, as my old friend Mr. C. B. Lockwood has often insisted, even when we see the appendix we cannot judge of it by its exterior; an apparently normal appendix is often like the "goodly apple," and it is becoming more and more evident that chronic appendicitis is often responsible, either for intestinal stasis and its ill effects, for gastric or duodenal trouble, or, on the other side, for setting up most obstinate colitis, and that removal of the appendix will cure none of these conditions when once they are established.

I have been profoundly astonished at the rapidity with which extensive changes occur in the appendix by the following. I operated some years ago on a woman for a most troublesome left pyosalpinx. At the time of the operation the right tube and ovary were normal. I looked for and carefully examined the appendix, which was (externally) perfectly normal. The operation had been a long one, and I did not think I was justified by adding to its length. Just three and a half months after the operation the patient came back complaining of attacks of abdominal pain and constipation (there were no localising symptoms). I opened her abdomen again, believing I would find pelvic adhesions. There were no adhesions, but the appendix was now about four and a half inches long, dilated to the size of the little finger, with two large concretions in it at its tip, completely filling it. Mindful of this case, and being convinced of the entire absence of additional risk, I am personally in the habit of removing the appendix in all abdominal cases where the patient's condition is satisfactory, and I can get at it. (I do not suggest, of course, making an incision unnecessarily long, or making a second incision for this purpose.)

On the other hand, we must not fall into the error of considering every case of abdominal pain to be due to inflammation of the "nuciform sac" beloved by playwrights, and even cases of pain and tenderness in the right iliac region are not necessarily due to appendicitis. Many such cases need most careful and prolonged watching; the possibility of renal or ureteral calculi, gall-stones, calcareous mesenteric glands, early spinal caries, psoas abscess, sacro-iliac disease, and right ovarian or tubal disease have all to be considered, and the aid of the physician and radiographer is indispensable.

In all such cases every possible attempt should be made to diagnose the cause, and the patient's pulse and temperature should be observed for a considerable time. If we can exclude conditions other than those which require operation, then I believe an operation should be undertaken, and this may frequently be of an exploratory character. I have assisted a surgical colleague in operating on a lady whose only symptoms were pain and tenderness referred to the appendix region. At the first operation a diseased appendix was found, *also* an unruptured tubal gestation sac. After some months exactly similar attacks of pain occurred, and a considerable number of minute gall-stones were found to be the cause. The motto "Wait and see" is held by some to be an excellent one, but in chronic appendicitis, as in acute, the waiting may be too prolonged, and visual inspection may either (1) disclose more than is anticipated, or (2) be conducted in the post-mortem room.

J. K. M.

COLITIS

(*a*) Non-Ulcerative Colitis

1. **Acute Colitis.**—The treatment of acute non-ulcerative colitis is the same as that of acute diarrhœa (p. 299), as it is produced by the same causes, the presence or absence of actual colitis depending upon the severity and the duration of the irritation of the mucous membrane. When colitis is produced, the after-treatment requires to be much more prolonged than in simple acute diarrhœa; it does not differ from the treatment of chronic infective colitis.

2. **Chronic Infective Colitis.**—An attempt should be made to ascertain the source and the nature of the infection. Pyorrhœa alveolaris and other septic conditions of the mouth, nose and pharynx require treatment, and the possibility of contamination of the water supply and of milk or other food should be investigated; if there is any doubt, all water and milk should be boiled and no raw vegetables or fruit should be consumed.

Sour milk exerts a marked inhibitory influence on the development of intestinal organisms; it is consequently very useful in some cases of infective colitis, especially when the stools are offensive and alkaline. It is important that a pure and active culture of the Bulgarian lactic acid bacillus should be used in its preparation. All the solid, and many of the fluid, commercial products are either completely inactive or very impure, containing a large proportion of streptococci, with few or no lactic acid bacilli. Very little should be given at first in order to ascertain how the individual reacts to the treatment.

My experience of autogenous vaccines in infective colitis is not favourable, as I have seen the condition greatly aggravated by their use,

large mucous casts instead of small quantities of uncoagulated mucus being passed after the first injection.

In the majority of cases excessive putrefaction takes place in the colon. It is then advisable to give a diet containing a minimal quantity of animal proteins for some time. In this way putrefaction is greatly reduced and the absorption of toxins is so much diminished that symptoms of auto-intoxication gradually disappear. In some cases only a few days of this treatment are necessary, but in severe cases it may be advisable to continue it for as long as three months. At first no animal food should be given at all, milk and eggs being prohibited as well as meat. In severe cases it is advisable to begin with foods such as sweetened arrowroot and water, which contains little or no cellulose. During this period constipation may occur, and the bowels have to be opened by means of paraffin and, if this is insufficient, by the use of enemata; it is important, therefore, to increase the quantity of ordinary vegetable food as soon as possible. After some improvement has occurred in severe cases, and from the beginning of treatment in milder cases, milk can be given; after a short period eggs, and subsequently fish, chicken and meat can be added to the diet. If enemata are required a solution of some such antiseptic as sodium salicylate (30 gr. to 1 pint) should be used.

3. **Chronic Catarrhal Colitis.**—Chronic catarrhal colitis is most commonly due to the irritation of the intestinal mucous membrane by hard fæces. It is often aggravated by the injudicious use of aperients and excess of vegetable food leaving a coarse residue. Hence, when constipation is complicated by catarrhal colitis, liquid paraffin should be used instead of vegetable aperients, and the less coarse vegetable foods, and those which depend on their chemical rather than their mechanical properties, should be given. In chronic cases treatment by intestinal lavage at one of the health resorts mentioned in the article on constipation should be advised.

4. **Muco-membranous Colitis.**—Patients suffering from muco-membranous colitis should be treated with the object of removing the two underlying factors—the abnormal condition of the nervous system and the constipation. It is most important to discourage the patient from making minute investigations of his stools; he should be told to be satisfied if he feels better without looking to see how much mucus is passed.

In severe cases it is advisable to begin the treatment with an unstimulating diet, such as milk, to which arrowroot and other cellulose-free carbohydrates can be added. As soon as some improvement has occurred, and in milder cases from the onset of symptoms a generous mixed diet should be given. Thin and anæmic patients, who have often unwisely restricted their diet, should be encouraged to eat, as they are unlikely to recover until they have gained weight. The diet should contain a plentiful supply of those articles, which are useful in uncomplicated constipation, on account of their chemically stimulating properties, but salads, pickles, fibrous vegetables, the skins and pips of fruit, whether raw, cooked or in jam, and the coarse varieties of whole-meal bread and oatmeal, should be avoided; in severer cases green vegetables should be passed through a sieve and given as purées. Mustard, pepper and spices of all kinds should be prohibited. It is desirable, especially when intestinal sand is passed, to replace as far as possible the saturated fats, such as stearin and palmitin, which form a large percentage of the fat in meat, butter, cheese and cream, by unsaturated fats, such as olive oil. It is most important that the food should be thoroughly masticated.

At the beginning of treatment every trace of fæces accumulated in the colon must be removed. This can best be done by the combined use of castor oil and enemata. Once the colon is empty, the re-accumulation of fæces can often be prevented by the administration of liquid paraffin or agar-agar in order to soften the stools. If a satisfactory stool is not passed each day, the further treatment depends upon whether the X-rays have shown that the stasis is in the proximal part of the colon, in which case aperients are required, or in the pelvic colon, when treatment by enemata without aperients is indicated. In most cases the best aperient is castor oil, half an ounce or an ounce taken last thing at night or on waking in the morning being generally required, but in some patients senna pods or saline aperients act better.

As in the case of uncomplicated spastic constipation, belladonna is the most useful drug for combating the intestinal spasm, but in many cases small doses of bromide should also be given in order to diminish the irritable condition of the nervous system. When the pain is severe it may be necessary to add codeine to the belladonna; the patient should be kept in bed and warm applications made to the abdomen.

Local treatment of the mucous membrane of the colon by means of enemata should only be used when other treatment has failed to give relief. As the patients are always self-centred they should not be encouraged to concentrate upon their bowels by irrigating the colon unless this is absolutely necessary. I have, indeed, seen improvement result from discontinuing intestinal lavage, which had been continued for too long a period, almost as frequently as from a course of the same treatment given to

patients who had not previously tried it. Intestinal lavage can be given at home, but it is generally more effective when carried out at Plombières, Châtel-Guyon, Harrogate, Llandrindod Wells, Bath or Buxton. Normal saline solution should be used if the treatment is given at home, and injections of soap and water, antiseptics and astringents should be avoided, as they tend to aggravate the condition by irritating the mucous membrane. At the various spas the natural waters are generally used for the purpose. The effect of the intestinal douches is much increased if the bowels are previously opened, either naturally or with the aid of a mild aperient, or an enema of olive oil or paraffin, given the evening before and retained during the night.

Various operations have been performed for intractable cases of muco-membranous colitis. When any condition, such as appendicitis, which is amenable to surgical treatment, appears to be the cause of the muco-membranous colitis, this should, of course, be dealt with. In the very exceptional cases, in which all other treatment fails to relieve the associated constipation, especially if the latter is due to stasis in the proximal as well as the distal colon, an appendicostomy should be performed, so that the colon can be washed out through the opening with two or three pints of warm normal saline solution every morning if possible, after the bowels have acted naturally. The irrigations should not be discontinued until at least three months have elapsed since the disappearance of all symptoms. The result of the operation is, however, not always satisfactory, and with the closure of the opening there is a considerable tendency to recurrence, as the underlying nervous condition remains unaffected.

Ileo-sigmoidostomy and colectomy should only be performed in the very exceptional cases in which the indications given in the section on the treatment of constipation are fulfilled.

A. F. H.

(*b*) Ulcerative Colitis

(*vide* also *Dysentery*).

If a sigmoidoscopic examination is always made when a patient passes blood or mucus in his stools or is suffering from diarrhœa, the cause of which is not obvious, ulcerative colitis can often be recognised at such an early stage that it is still amenable to medical treatment. Such treatment must always be prolonged, and no case can be regarded as cured until a further sigmoidoscopic examination has shown that all ulceration has disappeared. Symptoms frequently disappear weeks or even months before healing is complete, especially if the patient is kept in bed; this is the cause of the very frequent relapse after an apparent cure, but if all the ulcers have really healed there is no great tendency to recurrence.

The patient should be kept in bed until no blood has been passed for four weeks and the bowels are opened not more than twice a day. The rest of the treatment should be continued until no ulceration can be seen with the sigmoidoscope, but the diet should not be altered until three months later, and if the stools tend to become hard they should be kept soft with liquid paraffin for six months.

A generous diet should be given, and if, as is often the case, the patient has lost weight, two or three pints of milk should be given in addition. All food which could irritate the colon mechanically should be prohibited; vegetables are only allowed if they have been passed through a fine sieve, and no fruit except in the form of jellies should be given. Tough meat, porridge and whole-meal brown bread are prohibited. The indications for sour milk are the same as in simple infective colitis, and, as in that condition, pyorrhœa alveolaris or other sources of sepsis in the mouth, nose, or pharynx should be removed. All food must be thoroughly masticated.

In all cases the colon should be irrigated with astringent solutions every day. The bowels should previously have been opened naturally; if in the later stages of treatment there is a tendency to constipation, sufficient liquid paraffin should be given to make this possible, but should the bowels even then be insufficiently emptied, a plain water enema must be given before the irrigation. A pint and a half of fluid should be run in very slowly at a pressure of not more than eighteen inches of water; the tube should only be inserted just beyond the anal canal, as otherwise it curls round the rectum and rubs the ulcers, which generally extend to the beginning of the anal canal. I have found with the X-rays that fluid injected in this way invariably reaches the cæcum, so that the whole of the ulcerated mucous membrane is treated, as the ileum is never affected. The fluid should be retained for gradually longer periods up to half an hour.

I have generally used silver nitrate solution for the irrigations, beginning with a strength of ½ gr. to 1 oz., and gradually increasing to 2 gr. to 1 oz. Recent investigations show, however, that albargin (1 gr. to 1 oz.) would probably be more efficient; it has the further advantage that the subsequent administration of an enema of normal saline solution in order to prevent the absorption of the soluble silver salt is unnecessary.

It is always advisable to examine the stools bacteriologically, and to test the opsonic index of the blood against the different organisms found. In my experience, however, vaccine treatment has generally very little effect, but

if the active organism is identified with certainty, vaccination may be tried in addition, though never as a substitute to other treatment.

Intestinal antiseptics have very little, if any, effect; if sour milk is given they would probably diminish or totally prevent its activity. When the diarrhœa is particularly severe opium may be required.

When for any reason a patient is not willing to undergo prolonged medical treatment, which necessitates at least four weeks in bed and sometimes very much more, when medical treatment does not produce rapid improvement, and, when the case is already chronic or unusually severe when it first comes under treatment, an appendicostomy should be advised. The indications with regard to diet and vaccine treatment are the same as if no operation had been done, and the bowel should be irrigated twice a day with the same fluids as are used for irrigations from the rectum. In the later stages liquid paraffin should be given to prevent the formation of hard stools, and the opening should not be allowed to close until two or three months after a sigmoidoscopic examination has shown that all ulceration has disappeared. A. F. H.

SURGICAL TREATMENT OF DISEASES OF THE COLON

The greatest difficulty in the treatment of diseases of the large bowel is often the making of an accurate diagnosis as to the cause of the trouble. The colon is a very inaccessible portion of the human body, and when the site of the disease is unknown it is not easy to diagnose the condition correctly, or to ascertain the position and nature of the lesion. There are, however, several means at our disposal by which we can obtain accurate and reliable data to aid us in diagnosing the cause of the symptoms and the situation of the lesion. Thus we have the sigmoidoscope, X-ray photographs taken after a bismuth meal or after the injection of bismuth solutions into the bowel, examination under an anæsthetic, and chemical and bacteriological examination of the stools. It is usually necessary to employ several or all of these in the same case, and carefully to compare the results, and examine them in reference to the symptoms and history before attempting to make a diagnosis. In any difficult case it is seldom either possible or feasible to attempt a diagnosis as to the condition present in the colon from a single examination. Most of the failures in treatment of diseases of the colon are due to the want of a correct diagnosis rather than to any mistakes or lack of knowledge in the treatment itself. The diagnosis is, therefore, a matter of primary importance.

Treatment of Congenital Abnormalities of the Colon.—Congenital abnormalities of the colon are comparatively rare and but few of them are amenable to treatment. The commonest forms of abnormality of the colon are those in which there is some failure in the descent of the cæcum; in other words, where there is some congenital abnormality of the mesenteric attachment. One of the most important of these is the condition in which the cæcum and ascending colon have a common mesentery, and any condition may be found between this and the whole of the cæcum and ascending colon being attached by the same mesentery as the small intestine. When there is a long common mesentery to the cæcal angle there is always a possibility of its becoming twisted and producing a volvulus. This condition is generally described as volvulus of the cæcal angle. Usually the twist occurs around the ileum as an axis. The twist may occur in either direction, but the commonest direction seems to be that from left to right. A volvulus of this description is an exceedingly serious lesion, as it may involve nearly three quarters of the entire intestine. Dilatation occurs rapidly, and the symptoms are very obscure, though it is obvious that some obstruction exists. The only treatment consists in opening the abdomen and discovering and untwisting the volvulus. This should be done through a large incision in order to get a clear view of the parts, as the condition found is usually exceedingly complicated.

Congenital Dilatation of the Colon.—The non-operative treatment of this condition consists in careful regulation of the bowels by means of aperients and enemata. Abdominal massage and the application of the galvanic current have also been advocated. Unfortunately, these are merely palliative measures and only act by preventing the onset of acute obstruction, which is liable to occur at any time. The only chance of curing patients with this condition lies in operation. It is, however, very important that the patient should not be operated upon during an attack of acute obstruction. Colotomy, which is generally a fairly safe operation, is exceedingly fatal in these cases. Out of fourteen cases treated by colotomy which have been collected by the author, no less than eleven died. This is accounted for by the fact that the colon owing to its immense size cannot be drawn out of the wound, and all that it is possible to do is to establish a fæcal fistula into the dilated portion. Owing to the great weight and thick muscular walls of the bowel in these cases, there is a grave risk that the stitches will be torn away and that the patient will die from acute peritonitis. Colotomy should, therefore, be either entirely avoided in treating cases

of acute obstruction, or the colotomy should be done above the affected bowel.

The best results in these cases have followed resection of the dilated portion of the colon. This is obviously an exceedingly difficult and serious operation. The bowel in some of these cases may measure as much as nine inches in diameter and be an eighth of an inch thick. A considerable portion of the large bowel may be involved; great difficulty is therefore likely to be experienced in its removal, and it is not an operation to be lightly undertaken. Excellent results, however, have followed resection of the colon in these cases. In all but two of a number of collected cases in which this operation was performed the dilatation was confined to the pelvic colon. In one case, however, the entire colon was successfully resected for this condition. It must be noted that in three instances the dilatation of the colon has recurred after resection, and that a second resection has become necessary.

In one case the author performed appendicostomy for dilatation of the colon, the operation being done in the hope of preventing accumulation in the enormously distended sigmoid by washing out the colon daily. The patient, a man aged twenty-two, was quite well between the attacks of obstruction from which he suffered, and it did not seem justifiable to subject him to excision of the enormous loop of distended bowel unless every other method had failed. The results of this operation were very satisfactory, and no further attacks of obstruction had occurred up to two and a half years after the operation, at which time the patient was lost sight of.

Chronic Obstruction of the Colon due to Adhesions.—These cases form a very important group, as this condition is not infrequently accountable for the severe auto-intoxication which is occasionally met with, and to which considerable attention has lately been given. When a patient recovers from general peritonitis extensive adhesions between the different parts of the bowel are undoubtedly left; but there is abundant evidence to show that these may in course of time entirely disappear. Occasionally, however, for reasons which we do not quite understand, the adhesions remain and cause serious trouble. Where there are extensive general adhesions little is to be hoped for from operative treatment. Curiously enough, however, there is, as a rule, no serious trouble where the adhesions are extensive, and it is in the cases where there are a few localised adhesions that the most trouble results. The commonest situation for these localised adhesions is the sigmoid colon, and less commonly, the right flexure and cæcal angles. There is still considerable doubt as to whether these adhesions are congenital or acquired, though the writer is of the opinion that they are usually of an acquired character.

The diagnosis of such adhesions is often a matter of great difficulty, but the sigmoidoscope and examination by X-rays will usually render the diagnosis almost certain. Bands of adhesions causing kinking of the pelvic colon must be very carefully sought for, as they may be easily overlooked even when an exploratory laparotomy is performed. As a rule, little is to be expected from non-operative treatment in these cases beyond amelioration of symptoms, and usually before they reach the surgeon all the ordinary medical measures have been tried. Operative treatment consists in separating or dividing the adhesions and re-establishing the normal course of the bowel. It is further necessary, in order to prevent a recurrence of the condition, carefully to restore the peritoneal surface, so that no uncovered area is left which may be the starting-point of fresh adhesions. Many of the failures in the past have been due to insufficient attention being paid to this point. Most careful asepsis and hæmostasis are absolutely essential to secure a successful result in these cases. Where it is not possible satisfactorily to divide the adhesions, or where there would be risk in so doing, a short circuit of the obstructing angle, or resection of the involved portion of the bowel will generally be found to be the best treatment. The actual details of the operation naturally vary in every case.

Chronic Mucous or Membranous Colitis.—It is usually only in the worst cases of this condition that the aid of surgery is sought. But it frequently happens that purely medical treatment fails to give relief, and then, as a last resort the surgeon is called in. The opinion of the writer has always been that in the majority of cases in which the patient passes mucus in large quantities associated with abdominal pain and discomfort, there is no colitis in the direct sense; that is to say, the bowel is not inflamed. In these days by means of examination with the sigmoidoscope it is usually possible to distinguish those cases due to definite inflammatory lesion, and in these latter cases alone are satisfactory results to be hoped for from medical treatment. In the cases in which no colitis is found, the cause of the symptoms must be sought for in some other lesion in the abdominal cavity; and in the writer's experience such a lesion is nearly always present, though it may be difficult to find. Among such causes may be mentioned a chronically inflamed appendix, cancer, disease of the uterus or appendages, movable kidney, visceroptosis, gallstones, and aneurysm of the aorta. The obvious treatment, and the only

one likely to be successful is to find the cause of the symptoms and to remove it. This will often necessitate an exploratory laparotomy, as the diagnosis must frequently be in serious doubt. Such cases of colitis are always secondary and should not really be included under this heading, although, as already mentioned, they form a large percentage of the cases seen.

Apart from these cases surgery has attempted to deal with chronic colitis by two methods—(1) by establishing an artificial anus on the right side so as to give rest to the colon, and (2) by performing an appendicostomy which enables the large bowel to be kept constantly washed out. The first method, while sometimes successful, has now been completely discarded in favour of the second, which gives quite as good results and without any of the serious discomforts attached to a right-sided colotomy. Although it must be admitted that in many of the cases in which appendicostomy is performed a complete cure does not result, yet very great improvement is the rule, and in many instances it is possible to close the opening at the end of a few months. As appendicostomy does not cause the patient any inconvenience and the operation is not attended with any serious risk, it is well worth trying when other methods have failed, and should certainly be preferred to the establishment of an artificial anus.

Left inguinal colotomy has also been performed, but is quite unsound, as if the lesion is confined to the rectum it can be satisfactorily dealt with by local injections or ionisation, without having recourse to a colotomy; while if the disease involves the whole colon, no good results can be expected from a colotomy on the right side.

Ulcerative Colitis. — Up till comparatively recently cases of ulcerative colitis had been given no special treatment, or had been treated only by restricted and special dietary combined with attempts to wash out the lower bowel with antiseptic or silver solutions. It was found, however, that treatment on these lines was exceedingly unsatisfactory. A very large proportion of the patients died, the death-rate from ulcerative colitis at several of the large London hospitals being found to be nearly 50 per cent.; and, moreover, recurrences were very common, even when recovery occurred under such treatment. Out of sixty cases collected by the writer in 1910, thirty-three were treated medically and twenty-seven by operation. The mortality in the non-operated cases was 78 per cent., while in the operated cases it was only 22. It must also be remembered that at that time cases were only operated upon when they were practically *in extremis*, whereas now that the value of early operation is becoming recognised the mortality has been still further reduced. There is only one satisfactory way of treating cases of ulcerative colitis, and that is by immediate operation. The writer is of opinion that provided the cases are not left till too late recovery is almost certain with operative treatment. The best method is to perform an appendicostomy, and in the severe cases to follow this up with washing out the bowel every three or four hours with warm water; in the less severe cases irrigation twice a day will usually be found sufficient. It is to be remembered that many of these patients are very ill and are not able to stand a severe operation. Fortunately, appendicostomy is one which can be carried out quickly and without any serious disturbance of the patient. The results are very satisfactory. Bleeding and diarrhœa are generally controlled within forty-eight hours of the operation, and after this healing of the ulcerated areas occurs rapidly. At first it is wiser to use only plain warm water for the irrigation; in the later stages, where an astringent appears to be advisable, 0·5 per cent. argyrol or protargol may be used. On no account, however, should antiseptic solutions be pumped into the colon, as a serious amount of absorption is liable to occur. The irrigation of the bowel through the appendicostomy opening should be continued until the ulceration has quite healed and all symptoms have disappeared. After that it is not advisable to let the opening close for a full year, as relapses are by no means uncommon; they may, however, be easily dealt with as long as the opening is patent. At the end of a year, if there has been no relapse, the patient may usually be considered cured, and the opening can then be allowed to close up.

The formation of an artificial anus on the right side has also been tried in cases of ulcerative colitis; but it appears to have no advantages over appendicostomy, while it has several very obvious disadvantages. But in any case, whichever operation is performed, everything depends for success upon the operation being done early. In severe cases of ulcerative colitis patients go downhill very rapidly, and operation is not given a fair chance if it is performed when the patient is already in an exhausted condition with an extensively ulcerated colon, although even then excellent results are sometimes obtained.

Pericolitis.—This curious condition has only been called attention to within the last few years. In the typical condition there is a tight stricture, usually in the pelvic colon, often of a tubular character, and causing considerable tumour formation so that a swelling is often felt in the left iliac fossa. The condition is easily mistaken for malignant disease in the

sigmoid colon. In most cases the condition arises from diverticulitis of the colon, there being numerous little pouches or herniæ of the bowel containing fæcal concretions, around which chronic inflammation has occurred with the deposit of large masses of dense fibrous tissue. The stricture is, as a rule, densely adherent to the neighbouring parts. This condition is a simple inflammatory one and not malignant, although it closely resembles the latter condition. Chronic obstruction is the typical symptom which calls for treatment. In some cases, however, formation of an abscess or perforation of the bowel from the giving way of one of the diverticulæ is the first sign of trouble. The only treatment which can be of any use is operation. The ideal treatment is to resect the diseased portion of bowel and to sew up the ends so as to restore the continuity of the colon. This operation has now been performed successfully in a considerable number of cases, and the patients have completely recovered. In some cases, however, it is not possible, either on account of adhesions, the situation or the size of the stricture. The case may then be treated by short-circuiting the stricture or by the performance of an ileo-sigmoidostomy. As an alternative to this we may perform a colotomy above the strictured area, and where the patient is very ill or there seems reason to suppose that a short-circuiting operation is unduly risky, the formation of a temporary colotomy is the best treatment, and the question of removing the stricture may subsequently be discussed.

Tuberculosis of the Colon.—This condition is met with in three forms: (1) As part of a general or miliary tuberculosis. (2) Secondary tuberculous ulceration. (3) Hyperplastic tuberculosis. The last is the only condition in which tubercle occurs as a primary lesion in the colon. In the other two forms it is, as a rule, secondary to tubercle of the lungs; but in the third it certainly appears to be primary in the large bowel. As regards symptoms in diagnosis, hyperplastic tuberculosis of the colon closely resembles pericolitis due to diverticulæ. There is usually a large tumour and a tight stricture of the bowel, with great hypertrophy of the bowel wall. Except as a secondary complication ulceration is unusual. A very rare form is that called "gas-pipe colon," in which almost the whole length of the colon is involved, and is converted into a stiff strictured tube with thick walls, often mistaken for carcinomatous colon.

The treatment for this condition is the same as for pericolitis, namely, resection where possible, and short-circuiting, or exclusion with colotomy where a resection is not feasible.

The Treatment of Severe Cases of Chronic Constipation.—It is difficult to bring the treatment of this condition within the scope of a short article. The cases brought to the surgeon are those in which almost every form of medical treatment has been tried, and in which it is yet impossible, or almost impossible, to get the bowels to act with any regularity. The first essential in such cases is to ascertain the mechanical cause of the condition, if one is present. This is often a matter of considerable difficulty, but much help can be obtained by a sigmoidoscope examination, X-ray examinations, and careful examination of the patient. Where a mechanical cause can be found, such, for instance, as a chronic volvulus, adhesions, stricture, etc., the proper treatment is a laparotomy for the correction of the obstruction by suitable means. In those cases where there is no definite obstruction, and where the condition is due to a general atony of the bowel, the only treatment, if all medical measures fail, is appendicostomy, or in a few cases, ileo-sigmoidostomy.

Embolism of the Mesocolic Vessels.—This is a very rare condition, and one which is seldom diagnosed except on a postmortem table. The symptoms are those of acute obstruction in a patient in whom an embolus is probable. When the condition is diagnosed during life the only treatment which has led to success is resection of all that portion of bowel involved by the embolism.

Treatment of Tumours of the Colon

Simple Tumours.—Isolated polypi or adenomata of the colon are sometimes by means of the sigmoidoscope. They vary in size from quite small pedunculated growths to masses as large as a strawberry. They give rise, as a rule, to bleeding, and occasionally to intussusception. If left alone they tend to become malignant. The proper treatment wherever such a condition is diagnosed is the free removal of the polypus, together, if possible, with some portion of the bowel wall. There is a rare condition in which there are multiple polypi throughout the colon. Many hundreds, or even thousands, of polypi may be found scattered throughout the large intestine, and in such cases the patients suffer from very severe diarrhœa and bleeding. The condition is usually diagnosed by means of the sigmoidoscope, but the treatment is a matter of the greatest difficulty. There is a very marked tendency for one or more of the polypi to become malignant in course of time. The only treatment which would appear to have any serious chance of success is excision of the entire large intestine.

Malignant Tumours.—Cancer of the colon tends to remain localised and does not readily

give rise to secondary gland involvements or to metastatic deposits. The results of resection in such cases are often very satisfactory, and as quite large portions of the colon can be removed without seriously affecting the patient's subsequent health, malignant growths in this situation are particularly suitable for operative interference.

We must recognise the difference between treatment of a case of obstruction of the colon due to cancer, and the treatment of a case of cancer of the colon without obstruction. In the former condition the operation is performed for the relief of the obstruction, and in view of the very serious condition of the patient's health from the obstruction, an elaborate operation for the removal of the growth is not possible. All that can be done, as a rule, is to open the bowel above the growth; or, in favourable cases, to bring that loop of bowel containing the growth out of the abdominal wound. In the latter case a subsequent operation for the removal of the growth will be necessary. When, on the other hand, there is no obstruction present, a carefully planned operation can be carried out with the object of widely excising the growth, together with the contiguous portion of mesocolon and any glands in the neighbourhood. The ends of the bowel may then be sutured together so as to restore the continuity of the lumen.

The operation may sometimes be done in two stages, that portion of bowel containing the growth being first of all short-circuited, and at a subsequent operation the involved loop removed. This operation is particularly suitable in cases of cancer at the cæcal angle, and can often be used in cases where the left or right flexures are involved. Short-circuiting is also a good operation in cases of inoperable cancer of the colon, as it considerably prolongs the patient's life by preventing the possibility of obstruction.

The technique of these various operations cannot be gone into in this article. We can only say that very careful operating is necessary in order to obtain good results in cases of anastomosis of the large intestine.

J. P. L. M.

THE TREATMENT OF INTESTINAL OBSTRUCTION

The term "Intestinal Obstruction" includes three clinical conditions that differ widely in the pathological process giving rise to them and the clinical signs and symptoms produced. They call for accurate differentiation, since the success of the treatment employed depends largely upon the period at which it is undertaken. It is the custom to divide cases of this kind into three groups: viz. (1) Acute Intestinal Obstruction, (2) Chronic Intestinal Obstruction, and (3) Chronic Intestinal Obstruction becoming acute. This division, however, seems to imply that the difference between the groups is merely one of degree, and that the same causes are at work in all of them but with a varying intensity: this is not actually the case, and this fact should be kept in mind, since confusion of thought may lead to confusion in practice, which, in these conditions, may be attended with serious results.

It is difficult to suggest names for these three groups of cases that are not open to objection on the score of precision, but perhaps the following may help to keep before the mind of the observer the more prominent of the factors at work. The nomenclature suggested is as follows—

1. *Intestinal Strangulation.*—This group corresponds closely to that commonly called Acute or Sudden Obstruction, except that it obviously should embrace those cases of external hernia that have become strangulated: to exclude these from the cases of intestinal obstruction and to relegate them to a mere division of hernia is, perhaps, the best way of causing the practitioner to make the serious and common mistake of not inquiring and examining for an external hernia as the first step in the examination of any suspected case of intestinal obstruction. It is also open to the objection that those cases of obstruction due to thrombosis of the superior mesenteric vessels which are strictly included in this group cannot be regarded as cases of strangulation, but for all practical purposes it is very useful, since in all the members of this group—and there are many—there is a much graver cause at work than mere interference with the passage of the intestinal contents: the blood-supply of a portion of the bowel is interfered with, and it is to this factor that the speedily fatal result is due if prompt and efficient treatment is not adopted.

2. *Complete Intestinal Stasis.*—This term is not above reproach, since complete intestinal stasis must also occur in all cases of intestinal strangulation, but for want of a better it is used in this connection to denote the cases that are essentially chronic in nature, in which only the circulation of the intestinal contents—as opposed to the intestinal blood-supply—is interfered with and in which the obstruction has reached such a degree that neither gaseous nor solid matter can pass. This group corresponds to that termed chronic intestinal obstruction becoming acute, and is to be preferred inasmuch as the older term seems to infer that the type of obstruction has changed, whereas really it is only the symptoms that become acute, not the type of obstruction.

3. *Chronic Intestinal Stenosis.*—In this great group of cases there is only one influence at work, namely a gradually increasing difficulty in the onward passage of the intestinal contents. Eventually the obstruction may become complete.

A consideration of the foregoing classification will make it clear that in the first group of cases the main factor is sudden and severe obstruction to the intestinal blood-supply, followed rapidly by death of the affected area of the bowel: in the second there is complete occlusion of the intestinal lumen, leading to rapid decomposition of the arrested intestinal contents with resulting general toxæmia and local intestinal irritation; and in the third group there are the results produced by the efforts of the bowel to overcome the gradually increasing difficulty in the propulsion of its contents. It will be well before describing the prominent signs of each group of cases, to go into the differential diagnosis between intestinal obstruction as a whole and the various other conditions that may occur in the condition known as the "acute abdomen"; after that the symptoms special to each variety of obstruction and the appropriate treatment will be considered.

The Differential Diagnosis between Intestinal Obstruction and Other Forms of Abdominal Mischief.—Since it is common for a certain amount of *intestinal stasis* to occur in most acute abdominal conditions, it is obvious that the mere cessation of the passage of fæces and flatus is not in itself sufficient to entitle one to make a definite diagnosis. In cases of complete stasis, however, the patient is generally keenly conscious of his inability to pass anything, and often says that if he could do so he would be all right. Some *pain* is also complained of in all cases of "acute abdomen," and hence this symptom is not often very helpful unless inquiry elicits the fact that it was paroxysmal at its onset and was unaccompanied by tenderness in the earliest stages of acute strangulation: indeed, sometimes pressure seems to relieve it. The *vomiting* is rarely typical—and it is important not to wait until it becomes feculent. There is always an absence of *pyrexia* in cases of primary obstruction, and in those beginning with elevation of temperature some other cause must be looked for. This is a most useful point in diagnosis. Any case of "acute abdomen" beginning without elevation of temperature must be either an intestinal strangulation, a colic (hepatic or renal), a hæmorrhage or a perforation. The uncontrollable agony and intense collapse serve to distinguish a colic, while the signs of a hæmorrhage soon become obvious and a perforation will generally be made manifest by the sudden collapse followed by a rise in temperature and pulse rate. *Abdominal tenderness and distension* are usually absent in the early stages of the acute cases, but occur later on as toxic symptoms develop. In cases of complete stasis, however, they are early signs. We may summarise the symptoms of intestinal obstruction thus: In acute intestinal strangulation there is sudden acute abdominal pain, generally of a griping character and often relieved by pressure, followed in a very short while by violent vomiting which rapidly becomes "feculent." At the same time there is the characteristic "abdominal expression" and complete inability to pass fæces or flatus—at any rate after the lower bowel has been emptied. There is no pyrexia, the pulse is not rapid, and there is no abdominal distension. Later on distension occurs and the temperature and pulse rate rise.

In complete intestinal stasis and chronic intestinal stenosis there is little difficulty in the diagnosis—except in those cases of the former group in which no history of previous obstruction can be obtained. Even in these, the onset of complete obstruction is very obvious to the patient; and when this occurs in connection with an absence of pyrexia, and is accompanied by a painless distension of the abdomen and vomiting, persisting on the ingestion of food until it becomes feculent, there can be little doubt as to the cause, though the whereabouts of the obstruction may be uncertain.

The different conditions producing obstruction give rise to different symptoms and may call for different kinds of treatment. It will be well, therefore, to describe each variety and its treatment separately.

Intestinal Strangulation (*Acute Intestinal Obstruction*) occurs most frequently in the small intestine, and its most common causes are strangulation of a hernia (external or internal), strangulation beneath a band, volvulus and intussusception: to these must be added the acute obstruction caused by thrombosis of the superior mesenteric vein. The chief feature in these cases is the extreme urgency of the symptoms and the severe depression of the patient. The onset is sudden and is marked by sharp pain of a griping or colicky nature, soon followed by persistent vomiting which rapidly becomes feculent; there is complete obstruction to the passage of fæces and flatus. The patient always looks pinched and anxious, and may be severely collapsed. The pulse and temperature at first are normal and there is no abdominal distension.

In the case of an *external hernia* there are the well-known local symptoms of strangulation in addition, viz. increase in size, dullness on percussion, tenderness on pressure and irreducibility of the hernia. In the case of an internal hernia the pain may be localised, and after a

short time there may be definite tenderness on pressure over the site of the hernia.

An *intussusception* presents certain special features that should enable it to be diagnosed as such before operation. There is intestinal tenesmus with the passage of blood-stained mucus unaccompanied by fæcal matter, and the characteristic sausage-shaped tumour caused by the intussusception may be felt extending obliquely across the abdomen from the right iliac fossa to the splenic flexure. This alternately contracts and relaxes, and thus varies in consistency though it never disappears completely.

In a *volvulus* there is very early distension of the twisted coils of gut. The acute form of this condition is rare.

Treatment of Intestinal Strangulation (*Acute Intestinal Obstruction*).—The treatment of all these cases is to relieve the constriction by surgical means at the earliest possible moment. Not an hour's unnecessary delay is permissible. The diagnosis must be made as soon as possible after the patient is seen, and the abdomen opened directly arrangements can be made for doing so. There should be no attempt to wait and see what will happen; if the practitioner is in doubt as to whether the case is one of strangulation or not, it will be safer to open the abdomen at once and see the condition of affairs rather than to wait a few hours and give the bowel an opportunity to become gangrenous, as it will often do in a very short time. It is quite impossible to form any opinion as to the severity of the strangulation, or, therefore, of the rapidity with which gangrene will occur. No drug treatment is of avail. When the diagnosis has been made and arrangements are in progress for operation—and not otherwise—morphine may be administered. But when once this has been done, the operation must be carried out, however much improvement the morphine may appear to make. Before operation the stomach should be washed out to prevent flooding of the air passages during anæsthesia. The incision—in default of any localising symptoms—should be paramedian and sub-umbilical, and the further treatment will vary with the condition found and the state of the strangulated bowel. In all cases of hernia, the neck of the sac is dilated or divided and the hernia reduced; bands are ligatured at each end and removed; volvuli are untwisted, and an intussusception is reduced by squeezing the intussusceptum very carefully out of the intussuscipiens. When the strangulation has been relieved by one or other of these methods, the condition of the coils of bowel affected is inspected. If the peritoneal coat is shiny and has not lost its polish anywhere it is safe to close the abdomen and expect recovery, but if the bowel wall has lost its polish, and especially if any part of it has become dull and sodden and of a dirty greyish-black, the part will inevitably die and further steps must be taken. Small areas may be inverted by Lembert's sutures, but large ones demand immediate resection of the affected area and either immediate re-union, or the establishment of a temporary artificial anus followed later by a reunion. The choice between these methods depends largely upon the condition of the patient and the probability of his being able to stand so serious an operation.

Complete Intestinal Stasis (*Chronic Intestinal Obstruction becoming Acute*) may be due to any cause producing chronic intestinal obstruction (see below) and occurs when the degree of obstruction is so great that the intestinal contents fail to pass. The complete blockage may be temporary—as when it is produced by the irritation of purgatives or food above a stricture—or permanent, as in many cases of volvulus, intussusception, or kinks. In these cases there is generally—though not always—a history of previous obstructive symptoms such as constipation alternating with diarrhœa, flatulence, indigestion, and gradual increase in size of the abdomen. The completion of the obstruction is marked by entire arrest of the intestinal contents, which is accompanied by steadily increasing distension, increasingly painful peristalsis, and finally vomiting, which becomes feculent if allowed to persist. There is no elevation of pulse or temperature until secondary changes in the bowel wall set in.

The diagnosis in these cases is quite easy. The patient is intensely conscious of the obstruction, and for a long time it is merely the obstructive symptoms that are in evidence. Later in the case stercoral toxæmia sets in and may then overshadow the obstructive symptoms.

Treatment.—When the obstruction is complete, as it is in all these cases, the most pressing indication is to relieve the stasis and thus check the intestinal decomposition which, by the production of various toxines, not only produces local lesions of a severe type, but also gives rise to general toxæmia from which the patients frequently die. The urgency of the operation is not quite so great as it is in cases of strangulation, since there is no question of imminent gangrene of the bowel, but intestinal decomposition is going on all the time—even though the vomiting may be checked by withholding food by the mouth—and toxæmia is becoming established. Therefore operation should be urged without delay, and the practice of withholding food by the mouth, feeding by the rectum, and waiting on the chance of the obstruction giving way should be sternly discouraged.

There are two ways of relieving the obstructions met with in these cases. One is to open

up or remove the obstruction and so allow the intestinal contents to pass *per vias naturales*; the other is to establish an artificial anus above the obstruction without relieving the latter. The former procedure is obviously to be preferred when it is possible to carry it out, but reflection will show that in many cases it is fraught with so much danger that it is more in the patient's interest to carry out some other procedure. When the obstruction has lasted a considerable time, and especially when the patient is fat and elderly, the toxæmia already present may be so severe that no extensive operation is likely to be tolerated and it becomes clear that the one indication that the surgeon has to bear in mind is to remove the fermenting contents of the bowel as rapidly as possible, and with as little shock to the patient as may be, and postpone to a more suitable occasion all idea of radical procedures. One may summarise the methods at the surgeon's disposal thus—

1. Simple laparotomy and establishment of a permanent artificial anus. This is the operation of choice in an irremovable and unrelievable obstruction, such as cancer of the rectum.

2. Laparotomy and the establishment of a temporary artificial anus. This is the treatment for all those cases where the obstruction is removable, but the patient's age or general condition precludes this being done at the time the operation for relief of the obstruction is undertaken.

3. Laparotomy, removal of the obstruction and establishment of a temporary artificial anus. This applies to cases where the obstruction can be removed but the patient's general condition is too bad to render it safe to restore the alimentary canal after this has been done; a second operation for the restoration of the bowel can be undertaken when the patient recovers from the first.

4. Laparotomy, removal of the obstruction, and re-establishment of the intestinal canal without forming an artificial anus. This method is suited for cases in which the obstruction is due to a foreign body inside the bowel, pressure upon it from tumours outside, volvuli, or some of the rarer cases of malignant or innocent stricture in which the patient is comparatively young, the toxæmia very slight, and the operation for removal of the obstruction and repair of the bowel easily and rapidly performed.

5. Laparotomy, removal of the obstruction and immediate re-establishment of the intestinal canal with the formation of a temporary fæcal fistula in order to drain the bowel above the original seat of obstruction and obviate all risk at the line of union from distension or absorption. This is the best method to employ when the patient's condition and the nature of the obstruction allow of it. The fæcal fistula is allowed to close spontaneously, or, if it fails to do so, a plastic operation is undertaken for its repair.

Pending operation in all these cases all food should be stopped by the mouth, only water and such drugs as salol, β-naphthol, or boric acid, which tend to promote fermentation, administered. Lavage of the stomach often relieves the distress considerably and should always be practised immediately before operation. Morphine is only to be given to allay pain and check unduly vigorous peristalsis when operation has been arranged for.

Chronic Intestinal Stenosis (*Chronic Intestinal Obstruction*).—In these cases the symptoms of gradually increasing obstruction are quite clear, and the only difficulty in the diagnosis is the nature and situation of the obstruction. Gradually increasing abdominal distension, flatulence, indigestion, constipation alternating with diarrhœa and colicky attacks call the attention of both patient and doctor to the condition, and then careful search will reveal the cause.

Treatment.—Obviously this lies in removing the cause, and equally obviously this should be done before the patient has had time to suffer from toxic absorption from the bowel or generalisation of the disease should this be of an infective or malignant nature. An early laparotomy should be undertaken after all information has been obtained by means of bismuth meals, sigmoidoscopic examination and palpation under an anæsthetic, and any lesion found dealt with by appropriate surgical means. Medical treatment should only be indulged in while an attempt is being made to establish a diagnosis. F. F. B.

THE TREATMENT OF PERITONITIS

Acute Peritonitis

Acute Peritonitis may be *general* or *localised* to a particular region.

Acute General Peritonitis

The moment the diagnosis is made the surgeon's aid should be called in with the least possible delay. In this serious condition the only chance that the patient has of recovering is immediate laparotomy, which will give the surgeon an opportunity to remove the cause or to identify the organism to treat, by drainage, the accompanying peritonitis. It is evident, therefore, that the rôle the physician will play in this condition is (1) in the preoperative stage; (2) in the post-operative stage.

1. In the Pre-operative Stage

Position.—The patient should be put to bed in the position which will give him most ease;

this will usually be found to be in the semi-recumbent (Fowler's) position. A pillow placed under the knees, by relaxing the abdominal muscles, will also assist him. If this position is assumed the infection is restricted, as far as possible, to the pelvis; and further, when the patient is aged, to prevent any complication and reduce any distress falling upon the heart through flatulent distension, this attitude is of great value. If the patient complains of the weight of the bed-clothes, a cradle should be used.

Diet.—All food by the mouth is withheld, not only because a general anæsthetic may be at any time required, but also because the peristalsis which the ingestion of food stimulates, will be exceedingly painful and the movements of the intestines will open up channels for the dissemination of any purulent matter.

Thirst and Restlessness.—In addition the patient may suffer from thirst and restlessness. Both these may be relieved by the administration of rectal injections consisting of 10 oz. of a saline solution, 1 dr. to the pint, which may be given every two or three hours. Instead of this solution a 5 per cent. solution of glucose is sometimes used.

Medicinal treatment is in this stage entirely symptomatic. The most prominent symptom is pain; the only drug that will certainly give relief is morphia. It is of the very first importance that the symptoms should be left unmasked by the temporary amelioration afforded by the administration of morphia, for the most misleading picture may subsequently be afforded. If possible morphia should be rigidly withheld until after consultation with the surgeon. Once it has been decided to perform an operation there is no objection, if the pain renders its administration imperative, to a small dose hypodermically, *e.g.* $\frac{1}{5}$ gr. with $\frac{1}{100}$ gr. of atropine sulphate. "Pain and anxiety do more harm than a small dose of opium."

Hot stupes or fomentations to the abdomen very often afford considerable relief. These applications should be as light as possible in weight, and most conveniently take the form of thin cloths wrung out in hot water.

A complete examination should be made with as little disturbance to the patient as possible, to ascertain the condition of his heart and lungs and any other organs which will indicate the suitability or otherwise of a general anæsthetic, and supply any other information which may be of service to the anæsthetist.

Shortly before the patient is put upon the table he should empty his bladder, and when vomiting is taking place the stomach should be washed out with warm water containing sodium bicarbonate, 20 gr. to the ounce. In urgent cases this can be performed and a catheter passed when the patient is under the anæsthetic.

The preparation of the skin is of course left to the surgeon.

2. Post-operative Treatment

Position.—After the operation the patient is quickly put back in a bed thoroughly warmed with hot-water bottles, care being taken to protect him from any risk of being burned by them. An electric blanket is sometimes used instead of a hot-water bottle.

Immediate treatment to a large extent depends upon the condition of the patient. If there is much shock or collapse he must lie flat and the foot of the bed should be raised upon blocks. As soon as possible, however, the patient's position should be altered and the semi-recumbent, or Fowler's position, resumed. Once the patient has been placed in a comfortable attitude it is extremely important to alter his position as little as possible. Any such movement may set up an attack of vomiting, and in certain cases disturb the heart's action. Should the necessity for moving him arise, plenty of assistance should be procured in order that he may be shifted with the minimum of disturbance. Whilst the patient should be left alone as far as possible, constant watching is essential. There is never the slightest reason, indication, or justification for awakening a patient from sleep, and, indeed, sleep is often prevented by too active attention in nursing, or the too frequent giving of medicines. All mental excitement must be strictly prevented and visitors must not be permitted for at least twenty-four hours after the operation.

For the *shock* hypodermic injections of strychnine or adrenalin may be necessary.

Saline infusions should be started immediately. The most convenient method is by the rectum, but urgency may necessitate the administration subcutaneously or intravenously. When the stage of collapse has passed, saline infusions will still be continued, since by their aid the toxins are diluted.

In short, the effective treatment (apart from that of symptoms) resolves itself into the administration of as much fluid as possible, and this is best achieved by saline infusions. Normal saline is generally used, but the hypertonic solution known as Ringer's fluid is preferable. It has already been noted that the form of administration depends upon the urgency, and, if possible, the slowest form of all—rectal injection—should be selected. A malleable tube bent so as to lie on the bed is inserted for two or three inches, to this the ordinary infusion apparatus is attached. The temperature of the solution when it reaches the rectum

should be 100° F., and it should be allowed to pass into the rectum not faster than one pint an hour. A feeling of distension or other discomfort usually denotes that the fluid is being injected too rapidly, and this will be immediately relieved by retardation or stoppage of the flow. As a rule 4 to 5 pints will be easily borne, and much larger quantities have often been administered. The success or failure of the proceeding depends upon constant attention. Pituitary extract is valuable in combating the shock since it raises the blood pressure. Details as to the method of administration are given below under "Flatulence."

Vomiting.—Post-anæsthetic vomiting will usually continue for the first twelve hours, although in some cases hardly any disturbance of this kind occurs. It will generally be relieved by a teaspoonful of sodium bicarbonate in half a pint of warm water, which washes out the mucus and the remains of the anæsthetic from the stomach. As a variant, which is often more convenient, sips of hot water may be taken as frequently as possible. In more severe cases, a stomach tube may be passed and the stomach thoroughly washed out. Should this fail to stay the vomiting, opium must be administered. But again in this instance it would be as well to have a further consultation with the surgeon, for such a condition as strangulation, possibly the original cause of the peritonitis, may have recurred a second time; or again, while one cause of obstruction has been removed, there may be another still present.

Food.—For the first forty-eight hours after operation, any food taken by the mouth will probably be vomited, and therefore rectal alimentation alone should be relied upon. At the most a little iced water may be sipped, more particularly in relief of the thirst which invariably occurs, but which gradually disappears with the adoption of rectal saline infusions. Nutrient enemata should contain peptonised milk, beef tea and eggs, and a little brandy, notwithstanding the more than doubtful question whether any of these substances become absorbed. But even assuming that no nourishment is gained in this manner, the mental effect produced by their administration quite justifies the proceeding. After thirty-six to forty-eight hours, if progress has been satisfactory, sips of milk or milk and water may be permitted, roughly speaking about 1 oz. every hour. When once the bowels have been opened, feeding by the mouth may be increased. Peptonised milk is the best form with which to begin, and other articles of diet are added gradually in order of their digestibility.

Should vomiting occur at any period during this administration of food, further food should be withheld, and in this contingency the substitution of ice will sometimes help to stay the thirst and vomiting.

The Mouth.—It is important that the mouth should be kept as clean as possible, and antiseptic proceedings should be instituted as soon as the post-operative shock has passed off. Mouth-washes of listerine 1 in 20 or glycothymoline will be found pleasant as well as efficacious.

Flatulence.—To prevent or to relieve tympanites a rectal tube should be passed for six or eight inches up the rectum four-hourly. If relief is not obtained an enema of turpentine may be given on the second day: tincture of asafœtida has been found similarly useful.

A hypodermic injection of eserine salicylate, $\frac{1}{100}$ gr. every four hours for six doses sometimes gives relief, but a careful watch must be kept for any signs of overdose. Intramuscular injection of 15 min. of pituitary extract = 0·25 gm. of gland substance or pituitrin repeated in one hour has also been recommended for paresis of the intestines. Occasionally hot flannels placed over the abdomen will lessen the distension.

The bowels should be opened after twenty-four hours preferably by small doses of calomel repeated at frequent intervals.

Hiccough.—A most distressing symptom which frequently occurs is hiccough. Generally speaking the more serious the patient's condition, the more intractable the hiccough, which is regarded as either due to the inflammation of the diaphragmatic peritoneum and consequent irritation of the terminal fibres of the phrenic nerve or to the absorption of toxins. The most efficacious treatment is counter-irritation of the epigastrium or along the course of the phrenic nerve in the neck. This is best achieved by the application of mustard leaves, which may be accompanied by massage of the neck. Inhalation of amyl nitrite has often proved of service.

Cocaine ($\frac{1}{20}-\frac{1}{50}$ gr.), turpentine and musk occasionally may prove of value.

If all other measures fail and hiccough is wearing the patient out through want of sleep, morphia must be employed.

Heart.—Throughout the post-operative treatment the heart's action must be carefully watched, and it may at any time be necessary to administer small doses of brandy or a hypodermic injection of ether ♏ x, strychine hydrochloride ♏ v, or camphor gr. iii. in olive oil ♏ x. A valuable cardiac stimulant in these cases is caffeine soda salicylate, $\frac{1}{4}-\frac{1}{2}$ gr. hypodermically, which can be repeated after six hours and later four-hourly if necessary. It is not to be recommended in children, since it often produces nervous symptoms such as insomnia.

Pain.—A certain amount of pain is to be expected after any abdominal operation, and there is no particular urgency in alleviating it. But should pain occur of such severity as to prevent all possibility of the sleep which is so essential in the early post-operative stage, recourse must be had to morphine, the only drug which is of the slightest value. Heroin hydrochloride, $\frac{1}{24}-\frac{1}{12}$ gr., is a useful way of administering it. It is well, however, to remember that pain may be due to vomiting, to tympanites, to a tight bandage, or even to a distended bladder, exigencies which do not call for morphine but for obvious appropriate treatment.

As the whole of the direction and application of the necessary post-operative treatment may be left entirely to the practitioner in charge of the case, and not to the surgeon who has performed the operation, it has been deemed advisable to describe these details. It is, however, outside the scope of this article to deal with the question of after-dressings.

Serums and Vaccines.—The fluid removed from the abdomen at the operation should be microscopically examined and cultures made with a view to discovering the causal organism, its relative abundance and, if subsequently desired, to the preparation of an autogenous vaccine. If an immediate microscopical examination of the peritoneal fluid can be made, the causal organism may be identified and a stock serum instantly employed. Thus the appropriate immune serum may be intraperitoneally or intravenously injected, whilst the patient is still on the table, a procedure which will naturally utilise the serum to best advantage. It is difficult to give any general rule as to the subsequent use of serum, but for the principles involved the reader is referred to the article on vaccine and serum treatment.

It is solely on this point of specific therapy that any distinction with regard to treatment in acute general peritonitis need be made—according to the micro-organism found. This may be one or more of the following: bacillus coli, streptococcus, staphylococcus, gonococcus, pneumococcus, tubercle bacillus.

Of these the two most important and frequent are the bacillus coli and streptococci which are considered below. Further details are to be found under puerperal septicæmia and tuberculous peritonitis, but staphylococcal, gonococcal and that fatal variety, pneumococcal peritonitis, are rare.

With regard to specific immunisation the choice of treatment will lie between the injection of serum, ordinary vaccine or sensitised vaccine.

As has been stated already, bacillus coli infection is by far the commonest, and in this case either anticoli serum or vaccine of coli bacilli (or sensitised vaccine) may be employed alone or in combination.

Should the infection be the result of coli in association with streptococci then antistreptococci serum vaccine or sensitised vaccine can be given in combination with the anticoli serum or vaccine of coli.

Antipneumococcal serum or pneumococcal vaccine, sensitised or not, is used in exactly the same manner as the above. When the use of vaccines has been decided upon it may be convenient at first to use stock vaccines, and later, if need be, an autogenous vaccine.

Sensitised vaccine in large doses of the infecting organism may be started at the time of the operation by first injecting the stock sensitised vaccine and following this up later by sensitised vaccine prepared from the patient's own organisms.

The sensitised vaccine has the double advantage that it produces no diminution (negative phase) in the patient's resistance and has a quicker action in raising the resistance than the ordinary vaccine.

In addition to these specific measures a general leucocytosis may be produced by the injection of sodium cinnamate, nucleic acid, etc., thus a great increase of leucocytes will be observed twelve hours after 50 c.c. of 2 per cent. nucleic acid are injected.

Acute Localised Peritonitis.—This will occur in all cases of inflammation of any abdominal viscus, and will be met with most commonly in such conditions as appendicitis, gastric and duodenal ulceration, abscess of the liver, salpingitis, and subphrenic abscess.

Peritonitis is not only merely a symptom of the underlying condition, but its treatment merges entirely into that of the cause which has produced it. The management of such cases is, as would be expected, very similar to the pre-operative stage of general peritonitis, and the treatment the physician will apply will be of an expectant nature in the hope that the inflammation will subside and not take such a course that surgical interference is certainly indicated. The reader must, however, be referred to the individual treatment of the separate sections. It would be impossible here to do more than remind the reader of the controversy, which even to this day is held regarding the justification of treating such conditions as appendicitis expectantly. A considerable consensus of opinion advises immediate laparotomy in all cases.

For the benefit of the other school we describe the expectant treatment that may be adopted. The patient must be put to bed and at first nothing should be given by the mouth except a little water or albumen water. When the

acute stage has passed milk and Benger's food are added. Hot fomentations should be applied to the painful region of the abdomen and often with advantage these may alternate with ice-cold applications. These will generally prove sufficient to relieve the pain, but in some cases it may be considered advisable to give aspirin 10 gr. or phenacetin 10 gr. by the mouth.

The use of opium has already been considered in the opening paragraphs.

No aperients of any kind should be given, but an enema should be administered, and this often materially assists in dispelling the symptoms. The best enema consists of 2 oz. of olive oil; large soap-and-water enemata may, by distending the bowel, convert a localised abscess into general peritonitis.

The pulse-rate and temperature must be carefully observed, at least every two hours, and an examination of the abdomen should be made at the same time. A leucocyte count should also be made at intervals. The patient must be kept in bed until all signs have cleared up.

With this expectant treatment improvement must occur or other measures will be necessary. As the symptoms subside an aperient, *e. g.* calomel, may be given and solid food gradually permitted.

Chronic Peritonitis

may be: (1) of the *adhesive* type, local or diffuse, occurring as the sequel of acute peritonitis or of previous tuberculous peritonitis; (2) of the *proliferative* type in which great thickening of the peritoneum and ascites occur; (3) peritonitis associated with *new growth* of the peritoneum; or (4) peritonitis associated with *tuberculosis* of the peritoneum.

For the first variety medicinal treatment is of little avail. Inunctions of mercury and the internal administration of iodide of potassium have been recommended. The symptoms which occur are most often due to some obstruction and interference with the mobility of the various viscera as the result of the adhesions formed, and only surgical treatment will give relief.

The treatment of ascites with cross references for the treatment of the various causes is considered below and embraces therefore the treatment of the second and third varieties.

Tuberculous Peritonitis

Tuberculous peritonitis exists in one of two forms: the exudative or ascitic variety, in which there is fluid present in the peritoneum, and the dry or adhesive. The two forms will be considered together below, attention being drawn to any points of difference in the treatment.

The general treatment is similar as regards habit and diet to that of patients suffering from tuberculosis elsewhere in the body. This includes as much fresh air and sunshine and the most hygienic surroundings possible. The patient should remain in bed so long as fever is present, and in any case as much rest as possible should be enjoined.

Diet.—The diet should be abundant and nutritious. Solid food is to be preferred, and, unless it causes indigestion, a slight excess of fatty food, such as cream, milk, butter, sardines and bacon, should be ordered.

The medicinal treatment resolves itself into two classes: (*a*) general and (*b*) specific. Of the two, present opinion advocates the latter, and results are so satisfactory that the writer considers it the only line of treatment which should be adopted. Before this method was introduced patients suffering with this disease were given $\frac{1}{2}$ gr. of iodoform dissolved in $\frac{1}{2}$ oz. of cod-liver oil three times a day after meals, whilst at the same time equal parts of unguentum iodoformi and cod-liver oil were rubbed into the abdominal wall twice daily. Another method was to apply to the surface of the abdomen $\frac{1}{2}$ dr. of unguentum hydrargyri, the anointed part being subsequently covered with a flannel binder. This medicinal treatment was sometimes accompanied by laparotomy, the indications for which are considered below in the description of the operation.

Tuberculin treatment consists in the injection of minute doses of tuberculin (TR). It is usual to begin in the ascitic cases with $\frac{1}{100,000}$ mg. and gradually to increase the dose until the temperature is subnormal. The injections are given at intervals of 2–5 days. This may take five or six weeks, generally less. Even when the patient at the end of this time appears to be cured the tuberculin injections must be continued for at least six months longer. In the dry form of peritonitis, tuberculin is occasionally not so efficacious, and in any case it is as well to begin with a much smaller dose. The amount usually employed is $\frac{1}{500,000}$ mg. and is very gradually increased. During the course of treatment with tuberculin, should there be any rise of temperature or complaint of pain, the injections must be temporarily stopped.

Laparotomy.—In view of the successful results obtained with tuberculin injections, laparotomy is not now so frequently performed, but it may be satisfactorily combined with either the drug or tuberculin treatment described above. In any case undue haste should never be displayed, and unless the accumulation of fluid distresses or shows signs of increase, at least four to six weeks' trial of medical treatment should be allowed before an operation is sug-

ted. On the other hand, operation must , be postponed too long, since it will be a)eless procedure if the patient has general)erculosis or develops tuberculous lesions)where. The operation consists in making incision in the abdomen so as to expose peritoneum. The ascitic fluid is allowed escape and the wound is closed, no drainage e being utilised. The value of this pro-ure is unquestionable, for improvement nost invariably follows. Some surgeons irri-e with oxygen into the peritoneal cavity at time of the operation (Gordon Watson). the majority of cases one operation is suf-ent to effect a permanent cure, but occasion-r a second operation is necessary, and in this er contingency it is well to explore for some us such as a caseating gland, etc., which y be removed at the same time. This thod of treatment is of most value in the itic cases, and may be unavailing in the esive variety. The treatment after the ration should be on the same lines as ore: fresh air, full diet, tuberculin, etc.

ymptomatic Treatment.—At any time during attack the patient may be troubled by niting, diarrhœa or pain.

Diarrhœa.—For this 10 gr. sodium citrate y be added to every half a pint of milk en. Should this not prove effectual, a cture of bismuth and chalk to which small es of opium, appropriate to the age, may be ed. Tannalbin, 8–15 gr., forms a useful iant. The same treatment will serve to y the vomiting.

For the *pain* the best relief will be obtained m Pulv. Ipecac. Co. given in graduated doses ording to age, allowing ½ gr. for each year, to a maximum of 15 gr. three times a day.

The *convalescence* of the patient is most im-tant and a holiday at the seaside or in the ntry is essential. The general health can built up and the anæmia cured by tonics h as cod-liver oil, iron and arsenic. For purpose syrup of iodide of iron or Syrup cerophos Co. are the preparations most quently employed.

Ascites

Ascites may be due to so many causes that scheme of treatment will be best considered ler the headings of *general,* which is more or applicable to all varieties, and *special* ere particular treatment is required according the cause.

General. *Habits.*—The patient must, if possi-, be kept in bed and the position which gives most ease is one in which the head and ulders are raised, since this does not allow fluid to press upon the diaphragm. In se cases which have been tapped or cannot for any reason be kept in bed, a binder or abdominal belt will give great comfort by its support.

Diet.—The amount of fluid should be gradually reduced so that the patient does not drink more than a pint or a pint and a half a day. During this process it is important to avoid causing great thirst or constipation which follow the restriction of liquids. A salt-free diet is usually advised in order to prevent the retention of chlorides. Farinaceous foods and vegetables produce fermentation and flatulence, and so must be prohibited. Irritating articles, *e. g.* pickles, spices, etc., should also be shunned and alcohol reduced to a minimum. A suitable dietary will include such articles as bread, butter, cream, milk, milky foods, junket, weak tea, eggs, fish, chicken, mutton.

The following treatment will be found the most effectual for the relief of the accompanying distension and pain—

1. *Antifermentative.*—All fermentable food must be forbidden and drugs administered which are credited with the prevention of fermentation. Guaiacol carbonate 3–8 gr., naphthalene tetrachloride 2–12 gr., or calomel $\frac{1}{20}$ gr. can be given three times a day.

2. *Carminatives.*—Ginger, cardamoms, tinctura carminativa, sodamint tablets or powdered charcoal are all useful. In more obstinate cases the following mixture may be tried—

Sp. Chlorof. ♏ xx
Sp. Am. Arom. ♏ xx
Sp. Cajuput. ♏ xx
p.r.n. ex aqua.

An attempt to disperse the fluid may be made by means of *purgatives, diaphoretics, diuretics* and *paracentesis.*

Purgatives.—Hydragogue purgatives are the most suitable and Pulv. Jalapæ Co. 30 gr. or magnesium sulphate up to 2 oz. are convenient. Another favourite remedy is to give two or three times a week the pill, Hydrarg. 5 gr. at night, followed in the morning by a Seidlitz powder or ½ oz. of magnesium sulphate.

Diuretics.—When the effusion is due to morbus cordis the only drug of any value is digitalis. In cases where the cause is not clear and there is no possibility of a renal origin, the following mixture may be of service—

Liq. Am. Acet. ʒ i
Sp. Æth. Nit. ♏ xx
Sp. Juniper ♏ xx
Inf. Scoparii ℥ i
Sig. t.d.s.

Other drugs such as copaiba, apocynum, etc., have their advocates.

Paracentesis Abdominis.—The indications for the performance of this operation are—

1. Dyspnœa, œdema of the lungs or pleural effusion, bronchitis, hæmoptysis, caused by the difficulty in breathing due to the peritoneal fluid.

2. When the amount of urine passed is scanty and is becoming progressively less.

3. When the fluid causes such distension that urgent relief of the pain is necessary.

4. When pressure by the fluid is evidently causing portal congestion with cardiac distress or severe hæmatemesis.

5. Signs of incipient delirium tremens or exhaustion.

The patient is propped up in bed, a many-tailed bandage is placed behind him. He must empty his bladder or a catheter is passed. The site of incision usually chosen is a point in the linea alba midway between the symphysis pubis and the umbilicus. If this point is dull on percussion the skin is prepared as for a surgical operation. A suitable trocar, one with a fine bore to prevent too rapid escape of the fluid and sufficiently long with a companion well-fitting cannula, is sterilised. A piece of rubber tubing is fixed to the cannula. It is pierced by the trocar in its passage into the cannula. In very nervous patients it may be advisable to freeze the skin or inject a local anæsthetic, but generally the instrument may be inserted without such preliminary. The trocar is then withdrawn through the hole in the rubber, which contracts and closes; the fluid then drains into a vessel placed at any convenient distance, pieces of strapping are placed over the cannula and a cradle is put over the patient, who is now left to drain. The fluid may run for as long as twelve hours; clotting in the tube may cause temporary cessation of the flow, which resumes if the clot be massaged along the tube. As the abdominal contents decrease the many-tailed bandage is gradually tightened.

When the fluid has ceased running, the cannula is removed and a collodion dressing is placed over the wound.

Half an ounce of brandy may be kept in readiness to administer if faintness occurs. There may be a little pain for the two ensuing days.

In malignant disease or in cases of recurring ascites an opportunity may be taken to inject an ounce of water containing 1 dr. of 1 in 1000 adrenalin chloride.

In recurring ascites operations such as draining the fluid into the crural canal by a bone bobbin (Gordon Watson) or omentopexy (Talma Morison) may be considered.

During paracentesis the accidents to guard against are—

1. Wounding a viscus.
2. Perforating a blood-vessel.
3. The introduction of septic matter.

Varieties of Ascites.—The special treatment required depends upon the cause.

1. *Cardiac.*—(See *Diseases of the Myocardium and Endocardium.*) The treatment will include absolute rest, purgation, diuretics, especially digitalis, but not *diaphoretics,* because of the heart failure they may induce. The following pills form convenient methods of administering—

Pulv. Digital. Foliæ gr. ss
Scillæ gr. ii
Pil. Hydrarg. gr. ii
(Matthew Baillie).

Pulv. Digital. Foliæ gr. i
Pulv. Scillæ gr. i
Calomel gr. i
Extr. Hyoscyami. gr. ii
(Guy's diuretic pill).

Digitalis can also be given with 5 or 10 gr. of diuretin or combined with 5 gr. of caffein citrate or with theocin sodium acetate 3 gr. Nativelle's granules of digitalin $\frac{1}{250}-\frac{1}{60}$ gr. are valuable. In those cases where digitalis is found to disagree strophanthus may be substituted for the digitalis.

2. *Renal.*—By renal dropsy is meant that due to acute nephritis and chronic parenchymatous nephritis. The dropsy which occurs in chronic interstitial nephritis is cardiac in origin and must be treated on those lines.

Diuretics must not be used, the kidneys must be spared as much as possible. Diaphoretics are permissible together with other means of stimulating the action of the skin such as hot-air baths, etc.

3. *Cirrhotic.*—(See *Cirrhosis of Liver.*)

4. *Syphilitic.*—(See *Treatment of Syphilis.*)

5. *Malignant.*—In this type it should be remembered that there is no advantage in restricting the patient's diet. A. S. W.

SURGICAL PRINCIPLES OF THE TREATMENT OF GENERAL PERITONITIS

Early diagnosis and early surgical intervention are admittedly the most important factors in successful treatment. With regard to diagnosis let it be admitted that it is not in the power of any man or body of men to diagnose the presence of early general peritonitis in the lower abdomen; the onset of peritonitis in the upper abdomen is usually accompanied with such grave changes that it can hardly be diagnosed, but in the lower abdomen, where it most frequently originates, only too often its early symptoms are masked. In children it may be observed that rigidity of the abdominal wall is a most deceptive symptom. Over and over again I have opened the abdominal cavity and found it full of septic fluid where there was no abdominal rigidity at all before. In children

the facial expression in my experience is least likely to mislead.

If the term "localised appendix abscess" had no place in our mental view there is no doubt many valuable lives would be saved.

Let it be clearly understood, for the same reason, that the man who decides in favour of immediate operation in every case where he is doubtful of his own diagnosis will never have reason to regret his decision.

Having decided on operation, no time should be lost, the patient should be kept still and in a sitting posture to avoid gravitation of septic fluid to the upper abdomen.

The lightest possible degree of anæsthesia should be used, in order not to add to the patient's vomiting and to the amount of poisons already circulating in his blood. There can be no doubt that spinal anæsthesia is of great use in these cases. Two points of vital importance in the operation are rapidity of operating and doing as little as possible to disturb the intestines. The search for a gangrenous appendix should be short, and if rapidly found it should be simply clamped, ligatured and divided, and a large tube pushed down towards its original position.

The largest obtainable rubber tube with lateral openings is then pushed down to the bottom of Douglas' pouch and a wick of gauze placed inside it and the wound closed rapidly.

No attempt should be made to clear lymph off the intestines—it is nature's protection and should be respected as such—all are at present agreed that it is equally unwise to disturb the folds of small intestine or attempt at all making what was once called "the peritoneal toilette"—drain thoroughly and leave the rest to nature should be our motto. It should not be imagined from this that our resources are now at an end—far from it. There is no surgical complaint where close attention and after-treatment can do more to win the day.

The patient should be put back in bed in a sitting position and kept in that position until all immediate danger from spreading of sepsis is at an end. The first endeavours made are to combat shock and continued septic absorption. Whatever be the cause of shock its treatment is now sufficiently clear. "Diffusible stimulants," ether, strychnine, hypodermic injections of alcohol and the like are all useless. It is fairly certain that in the condition of shock the system is "bled into the abdomen." Where the great veins of the splanchnic area are dilated the systemic circulation wants fluid and must have it, and this very physical need of fluid to maintain the circulation is of use in diluting the toxins in the blood. The rapid and dangerous method of intravenous injection is now discredited and abandoned. Fluid should be given into the loose tissues of the axillary flanks and buttocks through a needle from a Thermos flask at 104° F., one pint to one and a half pints at a time and repeated as often as the local swelling is absorbed, until the patient has passed beyond the first profound danger of shock. The fluid to be injected may be normal saline solution prepared from boiled water by the addition of B. W. & Co.'s tabloids, or a pint of 5 per cent. glucose may well be given, this being prepared in the same way; recent work would suggest that this is preferable. If there is need for subcutaneous injections at all, remember that they should be begun *before the patient has left the operating table.* Fluids can also be administered by continuous slow administration by the rectum through a small (No. 6) rubber catheter passed some six inches. The fluid is allowed to run in drop by drop, each half pint taking half to three-quarters of an hour to run in, and being steadily absorbed. The apparatus for performing this simple nursing detail (honoured by the proctologists as proctoclysis, a name suggestive of Mesopotamia) is well known. It should be clearly recognised that this procedure can only replace the steady drainage of fluid from the peritoneum. It is useless to combat against shock, and there are many persons who cannot tolerate or retain any fluid by the rectum (55 per cent. in children). It is my practice to employ it after all serious abdominal cases and more especially after all cases so long as there is a drain into the peritoneal cavity.

Within six to twelve hours of the operation our hope will be that the patient can take some fluid by the mouth. An attempt should be made with this *as soon as the patient asks for it* (a rule worth remembering), and, if successful, fluids should be steadily pushed. I never allow a patient in such case to be pressed to take fluids, and my experience is that if they ask for fluids they will not as a rule vomit them (always provided that there is free peritoneal drainage). The character of the fluid can be rapidly changed—begin with ice water, lemon ice water, lime ice water, iced barley water, iced albumen water, iced sherry whey water, iced clear soup or beef tea.

The next condition which will absorb our attention is that known as ileus or paralytic distention of the intestine or popularly "the wind." Once well established this is highly dangerous and may actually kill the patient with all the symptoms of acute intestinal obstruction. The moral in its treatment is prevention. Each surgeon has his own ideas as to prevention and treatment. In a short article like the present I can only give my own. I attach importance to the following—

1. Maintenance of the sitting-up posture.

2. Early and plentiful administration of fluids.

3. And, most important, continued hypodermic injections of pituitary extract (one vaporole, B. W. & Co.). It is my custom to give the first injection before the operation is over and repeat the injection every four hours for the first twenty-four hours, every six hours for the second twenty-four hours, stopping the injections if there is a satisfactory action of the bowels. Pituitary extract has a double effect, it increases the blood pressure and, more especially, it stimulates the muscular coat of the intestine.

4. Attempts should be made as early as possible to empty the intestine as a routine. I give one ounce of castor oil eighteen to twenty-four hours after the operation (I am convinced it is most unwise to delay it to a later time); in three hours this is followed by a turpentine enema—this is repeated in two hours if there is no result—and then 5 gr. of calomel are given; this is repeated in 1 gr. doses every three hours until 10 gr. have been given, a turpentine enema being given *before* each fresh dose of calomel and the calomel discontinued if there is a satisfactory action.

If the calomel does not act stronger purgatives should be given. I well remember one case which seemed hopeless and was rescued by 30 gr. of Pulv. Jalapæ Co. I have also given Croton Oil 3 min. The general opinion of nurses at the present time is that the continuous injections of pituitary extract make their task in relieving the bowels much easier. I believe that this is true.

It may be considered that once distension is relieved and the bowels properly opened immediate danger from septic peritonitis is at an end; and with regard to later complications we are not concerned here.

One last word. No case of acute septic peritonitis should be regarded as hopeless. Close by is certain death with outstretched hand, and shall the surgeon pause and leave the patient in that inevitable grasp? Even if the patient dies on the table I maintain he should have the chance of life given him. It is impossible to say that any case is hopeless; both in children and in adults I can reckon on a few recoveries in patients who were pulseless and *in extremis*—surely, therefore, the operation must in all cases that are just alive be undertaken, boldly and rapidly, whatever the risks.

VISCEROPTOSIS

The normal position of the viscera and its maintenance in different postures depend upon (1) the proper development of the thorax, and (2) the maintenance of the normal intra-abdominal pressure.

Insufficient development of the thorax is not infrequently congenital; it may also result during the period of growth from disorders of nutrition, thoracic diseases and from insufficient exercise. As the thorax is long and shallow, the thoracic part of the abdomen is abnormally small, and the liver, spleen and kidneys, and the part of the stomach which is normally hidden beneath the ribs, together with the colon, are displaced downwards.

The most common cause of visceroptosis, however, is a diminution in the intra-abdominal pressure. The viscera are normally kept in position by the slight positive intra-abdominal pressure, which is maintained by the tonic contraction of the muscles of the abdominal wall and the pelvic floor, their peritoneal attachments remaining slack. The position of the diaphragm also depends in part upon the difference between the negative intra-thoracic pressure and the positive intra-abdominal pressure; if the latter is reduced for any reason, the diaphragm and the organs which are attached to it descend when the vertical position is assumed. A fall in intra-abdominal pressure is most commonly due to weakness of the abdominal and pelvic muscles. Even when the abdominal and pelvic muscles are strong, the diminution in the bulk of the abdominal contents by the disappearance of the normal intra-abdominal fat, when for any reason a condition of emaciation develops, results in a fall of intra-abdominal pressure and consequently in visceroptosis.

When the contents of the thoracic abdomen are displaced downwards owing to its insufficient development, the viscera drop no more than those of normal individuals on assuming the vertical position. When, however, visceroptosis is due to low intra-abdominal pressure the viscera drop as soon as gravity comes into play, but at first they regain their normal situation as soon as the patient lies down. At a later stage, when the daily descent of the viscera has continued for a considerable time, the displacement persists in the horizontal position.

The symptoms present when visceroptosis is due to an ill-developed thorax are not caused by the ptosis, but by the general condition of malnutrition which is frequently present. It is therefore only necessary in this place to discuss the treatment of the form of visceroptosis which is due to low intra-abdominal pressure.

Prophylaxis.—Much can be done to prevent visceroptosis and the associated constipation in women by proper management of the puerperium. The patient should remain in bed fo

the first twelve or fourteen days after parturition, or, when much bruising has occurred, especially in the case of primiparæ, for as long as three or four weeks. The first few days after getting up should be spent for the most part on a couch, and a return to full physical activity should only be permitted after about six weeks.

Treatment.—Visceroptosis due to insufficient development of the thorax requires no special treatment. In all other cases the first indication is to raise the intra-abdominal pressure. In order to do this the condition of the abdominal and pelvic muscles must be improved. Exercise and Swedish gymnastics are of great value; massage and faradism are less useful.

It is essential to prevent the over-stretching of the muscles, which occurs as soon as the erect position is assumed, as it is impossible for them to regain their normal tone so long as they have to bear the weight of the viscera for the greater part of every day. In almost all cases, therefore, an abdominal support is required. It has sometimes been taught that a support should only be worn when the abdominal muscles are so weak that their recovery is deemed unlikely, as improvement in the condition of the muscles is supposed to be rendered impossible by the disuse-atrophy, which the support is believed to cause. This view is, however, erroneous; by relieving the abdominal muscles of the weight of the viscera, a support prevents them from being stretched, with the result that they generally regain much of their former strength. A support, moreover, often gives so much relief to the abdominal discomfort caused by visceroptosis that it enables a patient to eat more without fear of discomfort and to take more exercise, and so indirectly helps to overcome the sluggish action of the intestines, which may be present in addition to the dyschezia generally present as a result of the weakness of the abdominal muscles.

An abdominal support should fit closely to the symphysis pubis and Poupart's ligaments below; above it should not extend higher than the umbilicus. It should be so made that it presses the abdominal contents upwards, backwards and inwards. It is essential that it should fit well and cause no discomfort. In mild cases of visceroptosis in women all that is necessary is a special straight-fronted corset, which does not constrict the waist, but supports the lower part of the abdomen. In most cases, however, a light support hinged in the middle line and fixed in position by steel springs passing over the hips to end in pads applied to the sacrum is required. In severe cases, especially in very thin patients, a pneumatic pad should be fixed under each side of the support; this can be inflated with a pump by the patient, the degree of inflation being reduced as improvement occurs and the patient becomes stouter. Only in exceptional cases should a support be used with the object of supporting a single organ; I have several times seen a kidney pad produce serious digestive disturbances by pressing upon the colon or stomach, often without effectively holding the kidney in position. An ordinary visceroptosis support is sometimes all that is required to keep a movable kidney in position, but it may be necessary to have an extension with or without a pad added to the support.

The abdominal support should always be put on when the patient is lying down with the pelvis raised, so that the organs are held in proper position, and it should be worn all day. Not infrequently, however, the X-rays show that the stomach and colon drop on standing almost or quite as far when the support is worn as without it. This is particularly likely to be the case when an organ falls into the true pelvis, as the support does not then reach low enough, and in thin patients, upon whom it is impossible to exert sufficient pressure. In such cases, indeed, I have sometimes found with the X-rays that the support actually holds the organ down and prevents it from rising when the horizontal position is assumed. In numerous instances I have found that a support does not hold the colon or stomach up at all and yet the patient derives great benefit from wearing it. This shows that it acts chiefly by increasing intra-abdominal pressure, and that many of the symptoms ascribed to kinks are really the result of the low intra-abdominal pressure interfering with the circulation and with the proper performance of defæcation. It has, for example, been frequently said that mild cases of the so-called "ileal kink" can be relieved by the mechanical effect of an abdominal support which holds the cæcum up and prevents its development. No radiographic evidence, however, has ever been published to show that it does this, and my own radiographic observations show that nothing will hold a cæcum out of the pelvis, which remains there on lying down, and that it is even rare for a support to hold it out of the pelvis when it only falls from the right iliac fossa on assuming the vertical position. The effect of the support is thus general and not local in a large majority of cases.

When visceroptosis is due in part to weakness of the pelvic floor this may require treatment by pessaries and local operations, which have the object of restoring the injured parts to a more normal condition.

In slight cases of gastroptosis the patient should lie down for an hour after meals, but in severe cases of visceroptosis, in which there is great emaciation or the abdominal muscles are greatly atrophied, it is best for the patient to remain in bed for some weeks, as by this

means the intra-abdominal pressure is reduced to a minimum and all tension is removed from the abdominal and pelvic muscles; the foot of the bed should be raised as high as possible, as this helps the organs to return to their proper position, which is often maintained after the patient gets up again, especially if he gains weight during the rest.

As most patients with visceroptosis are thin they should be given a generous diet, as an increase in the amount of intra-abdominal fat helps to keep the viscera in position. The meals should be frequent and small in bulk, fluids being given apart from solids in order not to distend the stomach.

It is very important that a proper squatting attitude should be assumed during defæcation, and if a patient has an abdominal support he should wear it during the act. The dyschezia should be treated by graduated enemata (*vide Constipation*), until the muscles of defæcation have regained their strength.

Only in exceptional cases should any operation be performed for fixing dropped viscera. As one organ is rarely dropped alone, the effect of such operations is rarely permanent, and the neurasthenic condition of many of the patients makes surgical interference of any kind most undesirable. The chief exception to this rule is in cases of movable kidney, in which serious symptoms have resulted from obstruction of the ureter or blood-vessels and an abdominal support has not given complete relief. Short-circuiting operations are very rarely required for the purpose of overcoming kinks in the alimentary canal. Gastro-enterostomy is never followed by any improvement in cases of gastroptosis, but in rare cases of severe kinking at the splenic flexure a short-circuiting operation, such as an anastomosis between its limbs, may be required, and the results obtained are generally satisfactory. A. F. H.

DISEASES OF THE PANCREAS

There are two main sources of difficulty in treatment of diseases of the pancreas, one the difficulty in diagnosing all but the most obvious lesions of the gland, the other its comparative inaccessibility, approached as it is through a viscus with an acid secretion, whereas its own is alkaline.

Methods of diagnosis are not included in our present survey. I propose in the first place to lay down certain considerations which govern the treatment of pancreatic diseases in general, and then the details appropriate to special conditions.

1. *Dietetic Treatment.*—Pancreatic juice contains ferments which are capable of acting on all foodstuffs and is the only one able to split fat to any extent, the lipolytic power of gastric juice being of academic rather than practical interest. It therefore follows that when the pancreas is diseased, fats are badly borne, for not only are they lost, excess of unsaponified fat appearing in the stools, but by coating over the proteins they hinder their absorption and increase their putrefaction. Proteins are digested by pepsin and can therefore be given so long as a form is chosen in which they can be acted upon rapidly in the stomach, such as minced meat. Certain proteins like caseinogen can also be digested by the erepsin of the succus entericus, and can therefore be used, *e. g.* plasmon or protene, whereas egg albumen will not. In addition the relatively large amount of sulphur contained in eggs renders them very prone to putrefactive changes. Gelatin on the other hand, owing to the absence of aromatic amino-acids, is not so liable to these changes, and can replace proteins to a limited extent.

For the digestion of starch we have to rely upon the ptyalin of the saliva; it follows that to take advantage of this, starchy foods should not be given in a soft form such as ground rice, but in a dry crisp form like toast, biscuit or rusk, which, requiring thorough mastication and insalivation, reaches the duodenum already largely digested. Sugars like glucose can be absorbed without further digestion, while cane sugar, maltose and lactose can be digested by the succus entericus. But their use in pancreatic diseases is unfortunately limited by the diminished sugar tolerance often found. The limit of carbohydrate tolerance should therefore be determined in the way described under diabetes.

2. *Regulation of the Pancreatic Secretion.*—The acid of the gastric juice is the great stimulant to both the external and internal secretion of the pancreas. Accordingly, if it is deficient it should be reinforced by the administration of dilute hydrochloric acid, or better 15 gr. tablets of betain chloride (acidol) freshly dissolved in water after meals. This liberates nascent hydrochloric acid slowly in the stomach. On the other hand, hyperchlorhydria over-stimulates and finally exhausts the pancreas, thus helping to set up chronic pancreatitis. It should therefore be corrected by alkalies, including magnesia, after meals.

3. *Supply of Deficient Ferments.*—This presents difficulties. The simplest method would be to pancreatise the food before administration, but this is liable to impart a bitter, disagreeable flavour. If ferments are given with the idea of their acting when the duodenum is reached, they will be destroyed in the stomach unless enclosed in capsules capable of resisting gastric digestion, and then we can feel little certainty that they will be set free in the duodenum.

Keratin-coated capsules are supposed to be the best. Capsules of gelatin toughened in formalin are apt to escape undigested even in the healthy subject. Takadiastase has been given before meals for the digestion of carbohydrates. One or more $\frac{1}{4}$ gr. tablets of pankreon with meals may be given a trial. Holadin is said to contain all the external and internal secretions of the gland. As it has been repeatedly demonstrated that the internal secretion of the pancreas cannot be absorbed by the intestinal mucosa the advantage of its addition is problematical. It is given in capsules. Stockton states that he has been unable to convince himself that any such ferments produce any improvement in the general condition of the patient or in the stools. He adds that many preparations on the market are practically inert, and many combinations are self-destructive, provided they are made as described.

4. *Disinfection of the Pancreatic Ducts.*—There are two drugs which are known to be excreted by the pancreatic ducts, as well as by other channels. These are helmitol and aspirin, both of them disinfectant in action. Routine employment of them in doses of 5 to 20 gr. three times a day is therefore a rational procedure and should be given a thorough trial. But perhaps the most efficient means of ridding the pancreatic ducts of infection is to drain them by a cholecystostomy, which, if indicated, should not be too long delayed.

5. *Diminution of Intestinal Putrefaction* resulting from diminution or absence of the pancreatic juice. The dietetic factors in these conditions have already been considered. The value of sulphates is not confined to their aperient action, for by combining with putrefactive bodies they render them inert. They should not be given in a concentrated form for this purpose as they are then apt to provoke desquamation of the intestinal mucosa, thus facilitating the absorption of toxins. Small doses of calomel, boric acid, β-naphthol or naphthalene tetrachloride in 5 gr. capsules may all be given a trial.

Any chronic disease of the pancreas, accompanied by insufficiency of its secretion, will call for some or all of these methods of treatment.

Pancreatic Infantilism

Any chronic disease in a child may cause persistent infantilism. Rarely the pancreas is responsible, as in a case reported by Byrom Bramwell, in which the exhibition of a glycerine extract of the pancreas checked fatty diarrhœa and promoted growth. It is difficult, however, to be sure that this is not the same condition as that described by Herter as due to chronic intestinal infection and characterised by an overgrowth and persistence of the flora of the nursling period. Intestinal disinfectants are therefore also indicated.

Acute Pancreatitis

1. **Hæmorrhagic.**—This terrible condition is naturally very unfavourable for treatment. Even morphia may not be able to relieve the pain. The general view is that as operation may increase the shock, it should be delayed in the hope of the patient surviving until the more amenable stage of gangrene is reached. Bosanquet points out, however, that diagnosis is rarely possible on clinical grounds and that the conditions with which it may be confounded, such as perforation of the stomach, duodenum, or gall bladder and intestinal obstruction, are all such as to demand operation. And as he is able to show a recovery rate of 29·6 per cent. after operation, there is considerable force in his contention. Billington and Goodwin advocate the simultaneous performance of appendicostomy so that large quantities of saline can be introduced into the colon, but in view of the shock, anything which prolongs the operation is to be deprecated. Self-digestion may occur along the track of the incision into the gland, and should be met by smearing the edges of the wound with antiseptic ointments and by plenty of porous packing. Pawlow adopted this method in his experimental animals, after noting that the animals themselves kept the wound in contact with sawdust or even with plaster they had scratched from the walls. Otherwise the after-treatment is that appropriate to any laparotomy.

2. **Suppurative and Gangrenous.**—Every one is agreed that here the indications are for immediate operation. In Bosanquet's series of thirty-five cases operated on, the mortality was thirteen, giving a recovery rate of about 63 per cent. Ten cases not operated on all died.

3. **Pancreatic Mumps.**—This is the only benign form of acute pancreatitis. Its recognition is important lest it should be taken for one of the graver forms requiring operation. It is usually preceded by parotitis, when its nature will be clear; but exceptionally, like the orchitis of mumps, it may occur before the swelling of the parotids. The pulse tends to be slow, which distinguishes it from other forms of acute pancreatitis. Glycosuria hardly ever occurs. It lasts only a few days and the prognosis is good. It should be treated by rest in bed, hot applications to the abdomen, light diet and cooling demulcent drinks, such as barley-water flavoured with lemon. Morphia may be required. Strong purgatives are contra-indicated.

Chronic Pancreatitis

Alcoholism, syphilis and arteriosclerosis are factors in producing chronic pancreatitis, which

must be taken into account in its treatment. Glycosuria must be looked for at frequent intervals and treated dietetically if present. The general lines of treatment previously laid down apply particularly to chronic pancreatitis. Cammidge considers that if there is not definite improvement after a month's course of aspirin and helmitol, the operation of cholecystostomy should not be deferred. This seems a better operation than cholecystenterostomy, as any infecting agent escapes from the body and is not returned to the intestine, whence it might again ascend the pancreatic duct. If the bile escaping from the gall bladder contains a pathogenic microbe a vaccine prepared from this should be tried. The biliary fistula should be kept open for at least six weeks.

Pancreatic Calculi

The flow of pancreatic juice may be stimulated by drinking freely of water acidified by CO_2, or a dilute acid which increases the formation of secretin, the hormone to pancreatic juice. In this way it may be possible to wash out small stones, but these are less likely to be diagnosed. Injections of pilocarpin would have the same effect, but are more risky and are not to be recommended. Pancreatic calculi have been successfully removed by operation.

Pancreatic Cysts

The only treatment is operation by incision and drainage as soon as the diagnosis has been made. If postponed, troublesome adhesions may form, or there may be intracystic hæmorrhage, suppuration or extensive fat necrosis. Healing is usually slow and a fistula may result. Exploratory puncture or an attempt to remove the cysts is to be condemned. A consecutive glycosuria may call for treatment.

New Growth of the Pancreas

Operation is only possible where the head of the gland is not involved, and this is rarely diagnosed. The diet suitable for pancreatic disease in general should be given. Anodynes may be required externally and internally. The pruritus can be treated as described under *New Growth of the Liver*. Bosanquet suggests cholecystenterostomy to short-circuit the bile for the relief of pruritus. If an exploratory laparotomy is performed, this certainly might be done. The consequent disappearance of the jaundice has a good mental effect on the patient.

W. L. B.

DISEASES OF THE LIVER, GALL BLADDER AND BILIARY DUCTS

1. **Treatment of Catarrhal Jaundice.**—During the initial stages the patient should be confined to bed on account of the vomiting and the liability of the catarrhal process to spread. Calomel in ½ gr. doses every hour until six doses have been taken is considered the best treatment for the vomiting, though the occasional intolerance of some patients to this drug has to be remembered. It has the additional advantage of being aperient without causing drastic purgation, which should be avoided. Its cholagogue action is purely indirect, as anything which stimulates peristalsis of the intestines causes peristalsis of the bile passages also. Ten hours after beginning the calomel treatment, a Seidlitz powder should be given, for repeated doses of calomel, which are not effective in getting the bowels open, may easily set up mercurial stomatitis. Alkalies are indicated as solvents of mucus, and, if the vomiting persists, should be combined with bismuth salicylate. The following formula is a useful one—

Bismuthi Salicylatis gr. x
Sodii Bicarb. gr. x
Sp. Menth. Pip. ♏ x
Sp. Chloroformi ♏ v
Inf. Rhei ʒ ii
Inf. Gent. Co. ad ℥ i
Quartis horis.

As soon as the state of the stomach permits, the more active sodium salicylate should be substituted. The value of salicylates is twofold: they dilute the bile and help to disinfect it, being partly excreted by the bile ducts. The diet will naturally be light. Milk is usually recommended as the mainstay, but owing to its comparative richness in fat it is not really suitable and is often much disliked by the patient. I prefer to give barley-water flavoured with lemon, with the white of an egg and a teaspoonful of somatose or plasmon to each half pint. Tea is usually forbidden, though it is difficult to see on what grounds; jaundiced patients often crave for it, and, if made in the Russian fashion without milk, but with a slice of lemon in it, seems free from objection. If the practitioner feels reluctant to abandon milk, it should be separated or thoroughly skimmed to get rid of as much fat as possible, and then a grain of sodium citrate added to each ounce of milk to diminish curdling. Benger's Food, calves' foot jelly and lemon sponge are pleasant and can usually be taken without difficulty. Mineral waters of an alkaline type, like Vichy, Apollinaris or St. Galmier, may be drunk freely.

When the bile pigment has returned to the fæces, the patient feels much better, though still jaundiced; he can now get up and the diet should be cautiously increased. There is sometimes considerable depression during convalescence, for which strychnine and calumba may be given. Dilute nitro-hydrochloric acid, in

10 min. doses, is often recommended, but should not be given until all signs of obstruction have passed off. It may be noted that, apart from the inconvenience of the discoloration by bile pigment, the disagreeable symptoms are mainly due to bile salts in the circulation, which are responsible for the headache, depression, slow pulse and pruritus. The treatment of this last symptom is dealt with fully under *New Growth of the Liver*.

2. Treatment of other Forms of Jaundice.—Here the treatment depends upon the cause. In the new-born the slight "physiological jaundice" calls for no treatment. Severe jaundice of the new-born depends on septic infection of the umbilical vein, hereditary syphilis or congenital malformation of the bile ducts. The first calls for vigorous, though usually unavailing, treatment of the septic focus; the second, for antisyphilitic remedies; while, for the last, nothing can be done. It is hardly likely that the child could stand an operation even for a simple occlusion of the main duct, and the condition is often more complicated.

Obstructive jaundice in the adult may be due to gallstones and their results, cancer of the liver, bile passages, or head of the pancreas, and exceptionally to other forms of pressure from without. The treatment of each of these will be found under the appropriate headings. The possibility of parasites in the bile ducts must be borne in mind. Toxæmic jaundice occurs in certain specific fevers, with poisons such as phosphorus, arsenic and snake venom, and in various other conditions exciting catarrh of the smaller bile ducts. The treatment of the graver forms is as for *Acute Yellow Atrophy*. True hæmolytic jaundice is met with in the acholuric family type, in which there is undue fragility of the corpuscles. Splenectomy has been performed with good results. Epidemic catarrhal jaundice is treated on the same lines as the sporadic cases.

3. Acute Yellow Atrophy.—In the early stages the case will be treated as catarrhal jaundice; the patient should be encouraged to drink large quantities of barley-water and the like. With the onset of severe symptoms it is advisable to purge freely and to give saline infusions intravenously, or into the loose cellular tissues; as much as three pints may be given at about the rate of a pint an hour. The diuretic effect of the infusions may be increased by adding a drachm of sodium acetate to each pint of saline. Venesection has the advantage of removing the toxins while the infusion is diluting them. Theocin-sodium acetate in 2 gr. doses every four hours is a useful diuretic. Gastric sedatives, such as bismuth subnitrate, cerium oxalate up to 5 gr. every four hours, carbolic acid in 1 min. doses mixed with 2 dr. of water, at frequent intervals, or 1 min. of Tr. Iodi in 1 dr. of water every ten minutes, may be required for the distressing vomiting. As carbohydrate is the foodstuff most easily metabolised in this state, and as it appears to help the antitoxic action of the liver, dextrose should be given by the mouth or by the rectum, or, if necessary, with the intravenous saline; a suitable strength is 2 per cent. if sodium acetate is also given, 4 per cent. if it is not. On the analogy of puerperal eclampsia, morphia may be found useful for convulsions and delirium. Chloroform inhalations should not be given for the convulsions because of their toxic effect on the damaged liver.

Hollaender suggests that Freund's method of treating eclampsia by injection of the serum from healthy pregnant women should be tried for the acute yellow atrophy of pregnancy. It is to be feared, however, that the prognosis remains extremely grave whatever method of treatment may be adopted.

4. Treatment of Gallstones and their Results.—Gallstones are due to infection of stagnant bile by the B. coli, B. typhosus or, occasionally, some other organism. They are commonest in stout, middle-aged women, in whom all the conditions favourable to stagnation of the bile are present, for the outflow of bile largely depends on peristalsis and the movement of the diaphragm as well as on the rate of secretion. Constipation, sedentary habits, drinking too little fluid and tight-lacing will, therefore, all contribute to stagnation. Two cases of gallstones I have seen in patients under thirty were both in grossly and prematurely stout women who had obviously tight-laced to an extreme degree. Visceroptosis is an important factor, for it favours both constipation and infection of the bile ducts. Its greater frequency in women is probably largely responsible for their greater liability to gallstones.

Gallstones may remain latent in the gall bladder, causing no symptoms beyond hyperchlorhydria due to reflex spasm of the pyloric sphincter, attacks of flatulence and a deep-seated tenderness on pressure under the right costal margin when the patient bends forward, or tenderness in the right sub-scapular region. The presence of a zone of hyperæsthesia somewhere between the costal margin and the umbilicus on the right side in a patient with acid dyspepsia is suspicious of gallstones. Typhoid "carriers" will generally be found to be the subjects of gallstones.

The passage of the gallstones into the bile ducts produces an attack of hepatic colic. The pain may be so agonising as to make it advisable to give a few whiffs of chloroform before proceeding to further treatment. Then

a hypodermic injection of morphine tartrate, $\frac{1}{4}$ gr., should be given, with the addition of atropine sulphate, $\frac{1}{100}$ gr. This combination helps to dilate the bile ducts to their fullest extent, thus diminishing the colicky contractions while facilitating the onward passage of the stone. The dose may have to be repeated. I am accustomed to follow this up with 10 min. doses of tincture of belladonna every four hours, until the patient is fully under its influence. The addition of salicylate of soda in 10 gr. doses helps to dilute the bile as explained above, and on several occasions I have been rewarded by the passage of stones after this treatment. Hot applications, of which antiphlogistine is one of the most convenient, are grateful to the patient. Bain recommends mustard packs over the gall bladder.

Between the attacks treatment is directed towards regulating digestion and checking the formation of stones as far as possible. Dyspepsia is usually of the hyperchlorhydric type, combined with intestinal flatulence. Treating the hyperchlorhydria relieves some of the symptoms, but will not help to cure the patient, as it is due to a spasm which is protective in origin. The dietetic principles underlying treatment are that meat extracts, purins and condiments help to produce hyperchlorhydria; soft carbohydrates and green vegetables promote flatulence. The fats, while diminishing the secretion of acid in the gastric juice, depend on bile for their absorption, and if not absorbed they increase intestinal putrefaction by coating over the proteins; moreover, their influence in producing obesity must not be forgotten. The practical deductions from these considerations are: (1) white fish, eggs, cheese, mutton and chicken may be allowed, while soups, broths, liver, kidney, sweetbread and rump-steak should be forbidden until the hyperchlorhydria is checked. (2) Dry forms of carbohydrate, such as biscuits, rusks and toast, are preferable to bread, ground-rice puddings and the like, because they demand thorough mastication before they can be swallowed, and, therefore, undergo a considerable degree of digestion by the saliva. (3) Sweets can be selected from jelly, egg custard, omelette, junket and stewed fruit. (4) At first vegetables had better be barred altogether, for, though cellulose is an aid to peristalsis, it promotes flatulence. As the patient's intestinal condition improves this rule may be gradually relaxed. (5) Fats, in the form of butter, cream or fat meat, should only be allowed in small amounts, for the reason given above.

It is important that water should be drunk freely to prevent inspissation of the bile. Patients do not care to be told to drink water from the tap, preferring, as of old, the waters of Abana and Pharpar. It is well, therefore, to select a spring which is mildly aperient, slightly alkaline, and not too highly mineralised, such as Rosbach, Apollinaris, St. Galmier, Vittel (*source salée*), or Evian. The sulphur waters of Harrogate are recommended by some. Salutaris water has the advantage of not being mineralised at all.

As to drugs, calomel once a week, alkalies and salicylates may be used to advantage as in catarrhal jaundice. Urotropin and salicylates are both disinfectants which are excreted by the bile; as is also helmitol, a derivative of urotropin which can act in an alkaline medium. A course of these drugs is advisable in all cases. Bile salts are cholagogues and are often recommended, but I have not been much impressed by the result of their administration. In any case, it is important not to give them while there is still an obstruction to the duct, as this would merely add to the amount of bile salts in the circulation and thereby increase the headache, depression, pruritus and bradycardia. A convenient preparation of bile salts is the colalin tablet, containing $\frac{1}{8}$ to $\frac{1}{2}$ gr., which may be given three times a day, or, if preferred, the colalin laxative tablet may be substituted. The treatment of pruritus is dealt with under *New Growth of the Liver*.

It is difficult to believe that any drug has a directly solvent action on gallstones. As the stones are said to dissolve in normal bile, the restoration of a healthy secretion is the best, if not the only way, of effecting this. Large doses of olive oil were formerly administered with that object, because gallstones were thought to crumble in this medium. It is true that fatty concretions may be passed when large doses of olive oil are given, but these are merely calcium and magnesium soaps, which might be formed by any one thus treated. And olive oil can hardly be suitable treatment for obesity. Crumbling of a stone can only conceivably be induced if it were protruding from the ampulla of the duct into the duodenum. Yet it is not likely that the treatment would have had such a vogue if it never did any good. I suggest that it alleviated symptoms of hyperchlorhydria by inhibiting gastric secretion. But there are other methods of doing this without its disadvantages.

Many surgeons are in favour of operative treatment in all cases of diagnosed gallstones, maintaining that one never knows when serious complications may occur, which would render operation inevitable and, at the same time, more difficult. Such grave views are hardly justified and probably originate in surgeons chiefly seeing the more serious cases. It is said that gallstones may form again after operation,

but it is more likely that all the stones have not been removed from a loculated gall bladder. It must be admitted, however, that medical treatment should not be too prolonged if the patient is not definitely improving. The chronic irritation of gallstones may set up cancer of the gall bladder. Bain's view is that, if there is no diminution in the objective signs after three weeks, immediate operation is advisable, while, if progress is not marked during the next three weeks, surgical interference is indicated. This is a practical rule to work by, but, as he says, "the frequency of operations for gallstone disease is a distinct reproach to medicine," implying that earlier and more efficient medical treatment would reduce the number.

It will be generally agreed that recurrent effects of gallstone colic and septic complications, such as empyema of the gall bladder or subphrenic abscess, can only be treated by drainage, aided by appropriate vaccine therapy. But should a fistulous opening have occurred into the bowel, expectant treatment is justifiable and, indeed, advisable. In any case of operation on a jaundiced person, calcium lactate in 15 gr. doses three times a day for three days before operation should be given to diminish the tendency to hæmorrhage.

5. **Cholecystitis.**—The medical treatment of this condition is essentially the same as for cholelithiasis, being summed up in the administration of salicylate and helmitol to disinfect the bile passages, calomel for the bowels, and free ingestion of alkaline mineral water, with hot applications over the gall bladder. Should the temperature become hectic and the leucocyte count continue to rise, drainage of the gall bladder by operation must not be delayed. It must be remembered that cholecystitis is one of the causes of fever without physical signs, and that, if the infection is due to B. coli, as it often is, there may be marked leucopenia.

6. **Treatment of Abscess of the Liver.**—(a) *Single or Tropical.*—This condition, which is a sequel of amœbic dysentery, calls for immediate operation, but subcutaneous injections of emetine, as advised by Leonard Rogers have an extraordinary effect in checking the hepatitis which precedes the abscess and will probably assist recovery after operation. The great liability of the abscess to secondary pyogenetic infections necessitates a rigid aseptic or antiseptic technique. If the abscess is already discharging through the lung, postural drainage should be tried. The patient hangs head downwards over a table, and in this position is made to cough and squeeze his chest. This may be repeated five or six times a day.

(b) *Multiple.*—Septic infection may reach the liver by: (i) the bile ducts, *suppurative cholangitis;* (ii) the hepatic artery, when it is part of an arterial pyæmia; and (iii) the portal vein, *portal pyæmia.* The treatment of the first variety is dealt with under the complications of gallstones, while the treatment of the second is that of the pyæmia, of which it is a comparatively minor part. Portal pyæmia, as I have shown elsewhere, is almost always due to a collection of pus under pressure within the portal zone. Appendicitis is the commonest precursor of such a collection, and was responsible for thirty-four, or just over 40 per cent., in a series of eighty-four cases I collected. Once established little can be done beyond symptomatic treatment. Blood-cultures may be sterile for a long time, as the organisms may be limited to the portal area, so that an autogenous vaccine often cannot be prepared. Surgical interference is only occasionally possible owing to the multiplicity of the abscesses, though successful cases have been recorded by Treves, S. West and Morton. Aspiration of the abscesses is not to be recommended, and fatal hæmorrhage into the peritoneal cavity has resulted from it.

7. **Treatment of Diseases of the Portal Vein.**—Suppurative pylephlebitis is merely a part of portal pyæmia. The commonest cause of pylethrombosis is cirrhosis of the liver, and was responsible for eleven out of twenty-five cases I collected (44 per cent.). It occasionally happens in new growth of the liver, and in the less virulently septic infections of the portal zone. Gastro-intestinal hæmorrhages or signs of intestinal obstruction are the leading symptoms in cases with acute onset, ascites in those coming on gradually. Little can be done in the way of treatment. The obstruction cannot be removed, and the only chance lies in supporting the patient until an adequate collateral circulation can be established. Even then, if the hepatic parenchyma be much involved, recovery is incomplete and temporary. Anything predisposing to gastro-intestinal catarrh must be avoided. Diarrhœa is a means of relieving the portal congestion, which we should not be too quick to check. If constipation occurs it should be remedied. Resection of the thrombosed portion of gut is a desperate remedy. On the ascites diuretics have little effect. Paracentesis should not be too long delayed, and, in spite of the loss of albuminous material, is usually well borne; the operation should, of course, not be performed too near the navel. Hæmatemesis should be treated just as in gastric ulcer. The Talma-Morrison operation for opening up fresh paths for collateral circulation is considered under *Cirrhosis.*

8. **Treatment of Cirrhoses of the Liver.**—(a) *Alcoholic or Multilobular Cirrhosis.*—The indications are: (i) to remove the cause, (ii) to relieve gastric catarrh, (iii) to relieve portal

congestion, and (iv) to assist collateral circulation. Chronic gastritis is a necessary preliminary to the production of fibrosis in the liver by alcohol. This accounts for the very variable action of alcohol in causing cirrhosis, and for the exceptional instances in which other poisons, such as mytilotoxin, appear to produce the same effect. It points also to careful oral antisepsis as an essential part of the treatment. But no treatment will be of any avail should the alcoholic habit be persisted in, and if self-control is so broken down that voluntary abstention is not likely to be maintained, initial treatment in an institution will be necessary. To diminish both the craving for alcohol and the gastric catarrh, I am accustomed to prescribe—

Tr. Capsici ♏ ii–v
Ammon. Brom. gr. x
Sodii Bicarb. gr. x
Spirit. Menth. Pip. ♏ x
Inf. Rhei ʒ ii
Inf. Gent. Co. ad ℥ i
t.d.s. ac.

If there is much morning retching a copious draught of water containing a drachm of bicarbonate of soda may help to clear off the mucus from the stomach, even if it is vomited.

To relieve portal congestion saline aperients should be given in the morning. An effervescent preparation like a Seidlitz powder may be the most grateful. An occasional dose of Pulv. Jalapæ Co. is sometimes useful, but fortunately the bowels often tend to be loose without drugs. The diet should be on the lines laid down for chronic gastritis (*q. v.*).

The occurrence of meteorism is suggestive of the onset of chronic peritonitis. A drachm of Ung. Hydrarg. Oleat. should then be rubbed into the abdominal wall every day, and 3 gr. capsules of benzo-naphthol with $\frac{1}{4}$ gr. of menthol every four hours may be given to relieve intestinal flatulence. If ascites supervenes and respiration becomes embarrassed there is no object in delaying tapping. Its appearance is always an unfavourable omen, and its speedy recurrence after tapping increases the gravity of the prognosis.

With a view of relieving ascites and assisting collateral circulation various operative measures have been advocated. Of these the Talma-Morrison operation is the best known; the upper surface of the liver and the lower surface of the diaphragm are scratched to promote adhesions, and the omentum is stitched to the abdominal wall. It must be pointed out that the operation is limited in scope, and cases must be carefully selected. For, in the first place, ascites is not a "back pressure" phenomenon in cirrhosis, but the result of chronic peritonitis, and, in the second, blood returning from the alimentary canal, which escapes passing through the liver by any short circuit, will contain substances which are not yet prepared for assimilation by the tissues and may be in some degree toxic. Thirdly, I have noticed at a post-mortem examination twelve months after operation that the omental adhesions were extraordinarily non-vascular. Again, advanced cases of cirrhosis notoriously stand operation badly, and if it is urged that early cases are more suitable, it may be replied that such are most suitable for medical treatment. Some years ago I saw a case of cirrhosis in a middle-aged woman with violent hæmatemesis. She then became drowsy, indeed almost comatose, for several days, while leucin and tyrosin crystals appeared in the urine. Yet she made a good recovery, and two years later was apparently in good health, having remained an abstainer. This could scarcely be called an early case, and had she been operated on, would naturally have been claimed as a brilliant success for that procedure. The immediate mortality of the operation is high, 37 per cent., but complete recovery is claimed for 31 per cent.

(b) *Hypertrophic or Biliary Cirrhosis.*—Probably various conditions have been thus designated, but the term should be restricted to the form described by Hanot. It is curious that cases seem to have been less common since examination of the blood became a routine procedure, and I am inclined to believe that the later stages of splenic anæmia (Banti's disease) were sometimes formerly taken for Hanot's cirrhosis. While the pathology is in such doubt treatment is necessarily unsatisfactory. On the view that it is caused by toxins reaching the liver by the general blood stream and leaving it by the bile ducts, systematic use of hepatic disinfectants, such as aspirin and urotropin, should be tried. Careful investigation may fail to reveal the nature of the toxin, but in one case of mine with marked infantilism, a positive Wassermann reaction was obtained after a small provocative injection of salvarsan. Otherwise the treatment can only be symptomatic and should be carried out on the lines laid down for other hepatic diseases.

(c) *Pericellular or Congenital Syphilitic Cirrhosis.*—The treatment is naturally that of syphilis. Salvarsan should not be used, however, as an initial treatment. It appears to cause such rapid disintegrative changes in the affected tissues that severe toxic symptoms may result. A prolonged course of mercury and iodide is safer, and in any case should precede the use of salvarsan.

(d) *Capsular Cirrhosis.*—This is usually associated with chronic peritonitis, and its treatment is that of the peritonitis.

9. Treatment of New Growth of the Liver.—The only innocent tumour of the liver is angeioma, which never produces any symptoms and is simply found at post-mortem examinations on patients dying of other conditions. Primary sarcoma is very rare and runs a very rapid course. Secondary sarcoma may be melanotic or lymphosarcoma. Primary carcinoma is rare, and then generally starts in the bile ducts. Though malignant disease of the liver in general is commoner in males, cancer starting in the gall bladder is commoner in females, suggesting chronic irritation by gall-stones as a factor in its production. If carcinoma of the liver is secondary the commonest situations for the primary growth are the rectum, stomach and uterus. Malignant disease of the pancreas seldom leads to large metastases in the liver.

The dyspepsia will require treatment on the lines of other forms of obstructive jaundice. One of the most troublesome symptoms is the intractable pruritus. Hot alkaline baths may be tried or some of the following preparations: a lotion of 1 dr. of creolin and 1 oz. of glycerine, made up with 10 oz. of water; an ointment of 20 gr. of camphor, 30 gr. of menthol and 1 oz. of vaseline; a dusting powder of $1\frac{1}{2}$ dr. of camphor, $\frac{1}{2}$ dr. of zinc oxide and 1 oz. of starch powder; a paint, or inunction, of $2\frac{1}{2}$ dr. of ichthyol, 3 dr. of absolute alcohol and ether to 2 oz. Other preparations which may help are Eichhoff's superfatted ichthyol-salicylic acid soap, prepared by Muelhens, of Cologne, or 10 per cent. of anæsthesine in olive oil. The difficulty about external applications for the pruritus is that the itching is *beneath* the skin. I have found thyreoid extract, in 5 gr. doses twice or thrice daily, the best remedy, as it diminishes the production of bile salts to the presence of which in the circulation the itching is due.

X-rays may be tried, though the most that can be expected is that they will check the rate of growth. Operation is usually definitely contra-indicated, though Keen has collected seventy-six cases of resection of tumours of the liver, sixty-three of which recovered. When more than one lump can be felt removal is impracticable. With the establishment of diagnostic tests for malignant disease of the liver, it is to be hoped that exploratory laparotomy, which is not well borne, will have to be resorted to less frequently.

W. L. B.

TREATMENT OF DISEASES OF THE EXCRETORY SYSTEM

FUNCTIONAL ALBUMINURIA

Functional albuminuria is a condition which is common in males between puberty and adolescence; it is much less common in females of the same age. Dukes found it in 16 per cent. of all the boys entering Rugby school. It is sometimes called "postural" or "orthostatic," to betoken the fact that the albumen appears only when urine is secreted in the upright position. Thus, it is absent from the urine passed on rising. It has sometimes been called "alimentary" but this is really a misnomer, for there is no evidence that the amount of albumen taken as food can influence the appearance of albumen in the urine. A possible exception to this is, that some constituent of raw eggs may, by exerting a toxic effect on the kidneys, excite a transient albuminuria. Indeed, considering how complete the breakdown of food proteins into amino acids is, it is difficult to see how excessive ingestion of protein could excite albuminuria.

Severe physical exercise will excite albuminuria in most healthy young adults. Thus, Collier found it present in every one of the Oxford crew of 1906, after rowing a course. Cold bathing may also induce transient albuminuria in such persons presumably by driving blood from the periphery into the splanchnic area. The albuminuria of exercise (to which the name "physiological albuminuria" may well be applied) need not be further considered here.

The subjects of functional albuminuria are usually anæmic, weedy youths with a dull, heavy aspect and a tendency to fainting. Their hearts are often irritable, and the condition vaguely diagnosed in lads as "weak heart" is frequently due to this. The blood-pressure is often very unstable, varying from hour to hour, and altering with posture in a way that the normal blood-pressure does not. There may be a difference of 40 mm. between the pressure in the upright and recumbent position. Examination of the urine may show, in addition to the albumen, a few hyaline casts and frequently calcium oxalate crystals.

The condition is unimportant, except that failure to recognise it may cause a boy to be labelled as a chronic nephritic, and his career seriously interfered with. In any case of albuminuria in a boy or a young man, the diagnosis of a kidney lesion should not be made unless casts other than hyaline are discovered, unless the tension of the pulse is definitely and permanently raised; and unless there are signs pointing to cardiac hypertrophy In the absence of such evidence, the urine passed

first thing on rising should be examined. If this is free from albumen, the condition is almost certainly functional. Then 15 gr. of calcium lactate should be given three times a day for three days. At the end of this time the urine should be examined again. In functional conditions, it is probable that the drug will have checked the albuminuria. If so, no further anxiety need be felt. If the patient has been working hard (and the condition is very apt to occur under the strain of competitive examinations), he should have a holiday, and be told not to worry about his health. A tepid bath with cold sponging down the spine, followed by vigorous towelling, generally suits such cases. As to drugs, calcium lactate is usually prescribed on Sir Almroth Wright's view that the condition is due to diminished viscosity of the blood. This contention is by no means generally accepted, however. I have sometimes given digitalis in small doses, such as 5 min. of the tincture three times a day, to try and brace up the lax state of the vasomotor system. Possibly pituitary extract, with its power of increasing normal muscular response, may prove to be of more service. A good general tonic, such as strychnine, is generally indicated with iron if there be any anæmia. The condition soon rectifies itself when adolescence has passed, and any case of albuminuria in a patient approaching thirty should be regarded as probably organic, and not merely functional. In conclusion, the recognition of this comparatively harmless condition is of far more importance than its treatment.

W. L. B.

ACUTE NEPHRITIS

The dictum that "in acute affections we concentrate our attention on the diseased organ, whilst in chronic cases we keep the general condition of the patient more in view" applies particularly to the treatment of nephritis.

In acute nephritis, the dangers of overloading the inflamed kidney with nitrogenous substances is apt to be disregarded; whilst, in chronic nephritis, the restriction of diet is apt to be too severe. Our aim in acute nephritis must be to remove, if possible, the microbic or toxic cause at work and to ensure such physiological rest for the kidney as is practicable; to promote elimination of nitrogenous and saline waste by other channels; to treat complications as they may arise and to correct the resulting anæmia. In this way much may be done to steer the patient towards recovery, although we can do little to control the course of the inflammatory process.

The patient is naturally kept recumbent in bed. Horder advises frequently moving him from side to side and occasionally on to the chest. This simple method of combating with effects of gravity should be more extensively employed than it is. To guard against chills and to encourage free action of the skin, he should be clad in a flannel nightgown and placed between blankets. The room should be warm and well ventilated. If suppression of urine threatens, dry cups may be applied over the loins.

1. *Diet.*—Nitrogen retention is a prominent feature and a source of danger in acute nephritis, so that the free administration of milk usually recommended is open to objection, since cow's milk contains 4 per cent. of protein, which equals 0·56 per cent. nitrogen. It will do little harm to deprive the patient of nitrogen for a time, and Von Noorden advises restriction of the diet at first to simply fruit-juice, water and sugar. Where there is no nausea, I have allowed toffee, which, being composed of butter and sugar, throws no work on the kidney; it is generally appreciated by children and allays hunger. Barley-water, with a little milk added, may also be given, and as the patient improves the proportion of milk may be increased. It is quite unnecessary to give anything else for a few days, and the relatives' fear of starvation must be allayed by explaining the rationale of the treatment. It is well to avoid salt in any form, as it is often badly excreted and its retention increases œdema by raising the osmotic pressure of the tissues.

Flushing out the kidneys is usually advised, and to this end the patient is directed to drink large amounts of water, but the inflamed kidney will not excrete water readily, so that attempts at flushing it out really only increase the œdema. The total amount of fluid allowed in the day should not exceed three pints for an adult or one and a half pints for a child of twelve. It is true that after some days there may be a sudden diuresis; this, however, is not the result of treatment, but the first and surest sign of convalescence. It may be termed a critical diuresis, and, after its occurrence, the quantity of water and milk ingested may be considerably increased with advantage; then bread and butter, potatoes and cream may be allowed. Beef-tea, broths, and meat-juices are all to be condemned as imposing work on the kidney with very little corresponding nutritive advantage.

A drink prepared by adding a pint of boiling water to a drachm of acid tartrate of potash, half a fresh lemon and some sugar, stirred occasionally until cold and then strained, may be allowed throughout in moderate quantities. The tartrate and citric acid become bicarbonates in the blood, and, by making the urine less acid, may render it less irritating; moreover, any

diuretic effect they may have is at the expense of the œdema of the tissues.

2. *Elimination by Other Channels.*—Of these the simplest and best method is purgation. A drachm of Pulv. Jalapæ Co., followed by a drachm each of sulphate of magnesia and sulphate of soda in as concentrated a solution as possible, should be given at the outset and repeated as occasion arises. Diaphoresis is not nearly so satisfactory and certainly should not be carried to excess lest the heart may become depressed. It is usually sufficient to sponge the patient well with hot water, followed by friction with warm, dry towels. The warm room, the blankets and the flannel nightgown also tend to produce perspiration. In my opinion, more drastic measures are seldom advisable in acute nephritis, except possibly in impending uræmia (*q.v.*).

3. *Drugs.*—No stimulating diuretics should be given at all. Saline diuretics such as potassium citrate probably do no harm and, as explained above, help to render the urine less irritating. The following prescription may be useful and is mildly diaphoretic—

Pot. Cit. gr. xv
Liq. Ammon. Acetatis ʒ i
Sp. Æth. Nitr. ℳ xv
Aq. Camph. ad ℥ i
Sextis.

The addition of 5 min. of tincture of strophanthus and 3 min. of Liq. Strych. is advisable if the heart's action becomes weak.

4. *After-Treatment.*—Bed is, of course, imperative until blood has disappeared from the urine, and is advisable until albuminuria has ceased altogether. This may be impossible, since acute nephritis may have sown the seeds of chronic nephritis, but there is, nevertheless, a great advantage in prolonging the rest as much as possible.

Fish and eggs, and later vegetables, may be added to the diet as the albuminuria diminishes, but meat and meat extracts should not be taken for a long time.

For the resulting anæmia few things are better than the Liq. Ferri Acetatis, of which 15 min. may be given with 1 dr. of Liq. Ammon. Acetatis in camphor water three times a day.

It is important that all possible precautions should be taken against chills, and the loins may be protected by the wearing of a cholera belt.

W. L. B.

CHRONIC DIFFUSE NEPHRITIS

It would be generally agreed that the orthodox, conventional treatment of chronic nephritis includes the following principles—

1. Severe restriction of protein intake with exclusion of food rich in albumen, such as eggs. In severe cases absolute restriction to simple milk diet.

2. The estimation of the amount of urea in the urine is to be taken as a guide to the capacity of the kidney.

3. The kidney is stimulated to increased excretion by the use of diuretics.

4. Elimination by the skin is promoted by various diaphoretic measures.

I venture to assert that each of these principles contains, and, indeed, is based upon, a fundamental fallacy.

In Bright's disease we have probably been inclined to lay too much stress upon the albuminuria. In the chronic parenchymatous form, no doubt the drain on the albuminous constituents may become serious and a secondary anæmia may result. But such high degrees of albuminuria are uncommon, and we are beginning to realise that this one symptom has unduly dominated our conceptions of the disease. Von Noorden thinks that any wasting is just as much explained by the monotonous diet as by the loss of albumen.

Chronic Parenchymatous and Chronic Diffuse Nephritis.—Chronic nephritis is often sub-divided into parenchymatous, interstitial and mixed. The interstitial form, granular kidney, presents so many points of distinction that it will be well to deal with it separately. The present tendency is to regard all cases of chronic nephritis involving the parenchyma of the organ as diffuse from the first, though, naturally, the interstitial changes take longer to manifest themselves. It is certain that, when parenchymatous nephritis has existed for any length of time, there will be interstitial change as well. In treatment no special distinction has to be drawn between chronic parenchymatous nephritis and chronic diffuse nephritis. In the latter it is not likely that œdema will be a marked feature calling for special attention. As a prophylactic measure it is essential that the after-treatment of all cases of acute nephritis shall be thorough and prolonged. It is seldom possible to treat the cause of chronic nephritis; only in syphilitic cases and in those of possibly malarial origin can this be done. Confinement to bed is only advisable during exacerbations, when dropsy is extreme, or when uræmia is threatening.

1. *Diet.*—The tendency in the past has been to restrict the protein diet in chronic nephritis too much, probably owing to false analogies with glycosuria, whereas there are certain essential differences; thus, a certain minimum amount of protein is an absolute necessity, while sugar can be replaced to a considerable extent by other things in a diet. Again, glycosuria is usually preceded by hyperglycæmia, while there

is no excess of albumen in the blood before albuminuria occurs. On the contrary, in nephritis the damaged kidney allows normal proteins to escape. Moreover, the proteins of the food are broken down into small molecules of amino acids before absorption. The evidence that albumen can be absorbed as such and is able to "run through" the body will not bear investigation. It is difficult, therefore, to believe, on theoretical grounds, that the albuminuria of nephritis can be directly influenced by the amount of albumen in the diet. I have tested the point practically in a good number of cases of chronic nephritis, and have found that the addition of three eggs to the daily diet has had no effect on the albuminuria.

This is not to say, of course, that unlimited protein is good for the nephritic. We know now that the physiological amount of protein necessary in the day is less than was formerly thought. Chittenden has clearly shown that nutrition can be maintained on 50 to 60 gm. of protein a day. We may say, then, that the minimum protein allowance for a chronic nephritic is 50 to 60 gm. plus the amount of protein which he is losing in the urine. In a case of ordinary severity this will be about 6 gm. a day, which is the same amount of protein as that contained in one egg. Von Noorden has shown that the ordinary chronic nephritic can excrete his nitrogen satisfactorily so long as he does not take more than 94 gm. of protein in the day. Above this amount, elimination becomes irregular and uncertain. This may, therefore, be regarded as the practical maximum, while 50 gm. of protein may be regarded as the theoretical minimum. There is not, then, a wide difference between the theoretical and practical conclusion. We should naturally avoid meat extracts and cellular organs, such as liver, kidney and sweetbread, because they contain a large amount of purins, which are useless for nutrition and necessitate excretion by the kidney; according to Von Noorden, the damaged kidney excretes uric acid with difficulty. To give such substances is contrary to the principles of physiological rest, but we must equally avoid such restriction of the diet as to lead to failure of appetite and consequent wasting while incapable of diminishing the albuminuria. We can safely permit a much greater variety of diet than is usually allowed; for instance, I believe from my analyses that eggs and dishes made from eggs certainly may be allowed. The eggs should not be taken raw, because raw eggs contain certain indeterminate substances which may have an irritant effect upon the kidney. The distinction drawn between red and white meat is fallacious. Red meat is assumed to have a more injurious action, presumably because it is supposed to contain more purin bodies, but the reddest meat, such as rump-steak, contains far less purins and other extractives than a white meat such as sweetbread. Again, mutton contains less purin than chicken. The practical conclusion is that small quantities of fish, mutton and ordinary beef may be allowed, while soups, broths, internal organs and rump-steak should be forbidden. But within these limits a wide variety of choice may be permitted. It is undesirable to restrict chronic nephritics to milk, which is too dilute a form of food for them and may increase œdema. Salt should not be allowed, since it is badly eliminated in many cases of nephritis and, accumulating in the tissues, increases œdema by raising their osmotic pressure. Indeed, as Bryant found, even a man with a healthy heart and kidneys may develop œdema as a result of taking excess of salt. The substitution of fresh butter and lemon-juice will usually satisfy the patient.

In following this plan, we shall avoid adding to the miseries of sufferers with an incurable disease by enforcing unnecessary restriction. If it be desired to guard against the dangers of possible nitrogen retention, Ernberg's plan may be followed of interposing periods of a week or a fortnight during which a diet poor in protein is taken. But prolonged nitrogen starvation is as bad for the nephritic as for any one else.

Generally speaking, alcohol is inadvisable in any form, and should never be ordered to those unaccustomed to it. In the case of patients in the habit of taking it regularly, deprivation may interfere with their appetite, in which case a little well-diluted whisky is probably as innocuous as any form of alcohol can be. But the strictest moderation must be enjoined.

Tea and coffee are usually forbidden because of the methyl-purins they contain. Although this is theoretically sound, many patients find this restriction very onerous, and, if there is no sign of exacerbation, I have allowed moderate quantities of China tea (which contains only about half as much purins as Ceylon tea) made weak and with plenty of milk, or made in the Russian manner with a slice of lemon.

2. *Determination of Urea Output.*—Within wide limits, the amount of urea excreted depends on the amount of protein eaten and on very little else, since the greater part of the urea comes direct from the food. It is incorrect to suppose that the amount of urea excreted is any real guide to the severity of the case or provides any indication as to the degree of restriction necessary in the diet. Of course a patient on the diet ordinarily given in nephritis passes less urea than a normal individual, since he is given a diet poor in protein. The more the diet is restricted, the lower will be the output of urea. The only help which can be got from

estimating urea is in conjunction with the total output of nitrogen as determined by Kjeldahl's method. Then it can be seen whether a proper percentage of the nitrogen is converted into urea. This should not be less than 80 per cent. of the total. But simple estimations of urea without determining the protein intake and the total nitrogen output are useless, misleading and should be abandoned.

3. *Diuretics.*—Flushing out the kidney is generally regarded as a good line of treatment in chronic nephritis, but before employing it we should consider what method of diuresis we mean to use, how far such methods are desirable in an individual case, and how far they will achieve the end desired. Routine and indiscriminate "flushing out" is to be condemned.

The following are possible methods of producing diuresis: (*a*) by vaso-dilatation in the kidney, as by caffein, theobromine, theocin sodium-acetate or diuretin. These probably act as direct stimulants to the renal epithelium, the vascular change being secondary. (*b*) By vaso-constriction elsewhere, in consequence of which the blood pressure is raised and more blood is forced through the kidney. (*c*) Increase in the quantity of the circulating fluid: (i) by absorption of water from the intestines, as by giving the patient large quantities of fluid to drink; (ii) by increasing the osmotic pressure of the blood. The saline diuretics—citrates, acetates, etc.—act in this way, drawing water from the tissues into the blood stream.

How far are these methods desirable in the treatment of nephritis? The first group are stimulants, and it is doubtful policy to stimulate a damaged structure. I have seen bad results follow the use of caffein, theobromine and diuretin. It is chiefly in chronic parenchymatous nephritis that they are employed and there is a danger that they will cause a return of acute symptoms, such as hæmaturia. I have gradually come to the conclusion that this group of drugs is unsuitable for nephritis and that they should be restricted to those cases where diuresis is required and the kidneys are not organically diseased. The same applies to juniper and scoparium. An exception may be made in the case of theocin sodium acetate which in doses of 2 gr. twice a day may produce a distinct improvement. It appears to render the kidney more permeable.

As to the second method of diuresis, since the blood pressure is generally raised in chronic nephritis, it seems unnecessary to raise it further. Digitalis is the drug usually employed for this purpose, but modern research has tended to overthrow its claim to raise blood pressure in human beings, and its diuretic action is now thought to be purely secondary to its cardiac action. If so, it should only be used as a diuretic in cases where the heart is failing. Even here I have seen it fail when the blood pressure was already high and the failure of urinary secretion was due to a secondary back pressure.

Again, in chronic nephritis there is a defective adjustment of the kidneys to varying water supply. Von Noorden has shown that, whereas a normal individual with an average hourly diuresis of 52 c.c. excreted an average of 723 c.c. for three hours after drinking 1800 c.c. of Salvator water, the nephritic hardly showed any response of this kind. As in acute nephritis, the drinking of large amounts of fluid may therefore merely increase the œdema.

Yet it is certainly desirable to achieve diuresis in chronic parenchymatous nephritis if possible. The attempt to increase the urinary flow by increasing the osmosis into the blood is less open to objection, for, as explained under *Acute Nephritis*, since the extra water is drawn from the tissues, it will tend to diminish and will not increase the œdema. As in the later stages of acute nephritis, I believe the best diuretic is a combination of 15 min. of Liquor Ferri Acetatis with 1 dr. of Liquor Ammonii Acetatis. This has the advantage of helping to correct the secondary anæmia.

If this has not the desired effect, the reaction to drinking a pint of water may be determined, but, unless it causes a definite increase in the amount of urine, it is no good persisting with the flushing-out method. In the presence of œdema it is not likely to be successful. The reaction to 2 gr. of theocin sodium-acetate twice a day may also be determined, but it is well also to test the urine daily with tincture of guaiacum and ozonic ether for blood, and the drug must be discontinued at once if the slightest trace is found. In any case, it should only be used for a limited time, and only if necessary in view of the continued falling off in the amount of urine.

4. *Diaphoretics.*—The arguments for and against diaphoretic measures in the treatment of nephritis will be found under the treatment of Uræmia. Diaphoretic drugs seem to me to be particularly unsuitable in the routine treatment of chronic parenchymatous nephritis, as a moist perspiring skin would render the patient more liable to chills, always an outstanding danger in this disease. A course of hot-air baths if there is retention of salt and increasing œdema may sometimes be helpful. I have seen this produce diuresis, which can only be explained as due to elimination of salt and consequent lowering of the retentive power of the tissues for water.

5. *Purgation.*—Free elimination by the bowel is here, as in other forms of nephritis, a prime requisite.

The use of mercurials for this purpose is not free from risk, as the sufferer from chronic nephritis is specially liable to stomatitis. Few things are better to start a free action of the bowels than Pulv. Jalapæ Co., of which 1 to 2 dr. may be given to an adult. When there is much dropsy, Matthew Hay's method of giving 6 dr. to 1 oz. of magnesium sulphate in 1 oz. of water before breakfast may be tried. In this concentrated form it is apt to excite nausea; if not, it will be found very effective in producing a watery evacuation.

6. *Paracentesis.*—Removal of the ascitic fluid by Southey's tubes is seldom practised now, though simple incisions are sometimes made. The wounds are very likely to suppurate and the fluid will re-accumulate as long as the conditions remain unfavourable. Ewart recommends drainage of the fluid into the legs by adopting the upright posture; the fluid, which presumably is loaded with toxic substances, is thus removed from the vital organs.

7. *Climate* may prove a valuable help in the treatment of chronic nephritis. Egypt generally suits these patients particularly well. Algiers is also quite suitable. The wind and the more violent fluctuations of temperature on the Riviera render it much less advisable. In this country Ventnor, or anywhere on the south coast from Bournemouth westward, is the most suitable climate that can be obtained.

It may fairly be objected that I have attempted to destroy the basis for treatment without being able to put anything in its place. To a certain extent this is true. The kidney, once damaged by chronic nephritis, cannot recover, and the only thing which can be done is to attune the mode of life to a low key, subjecting the patient to as little strain as possible. He must be warmly clad and the kidneys protected from fluctuations of temperature as far as possible. He may have a considerable variety of food provided that the intake of protein does not fall below 60 or rise above 90 gm. in the day, and provided that he takes very little purins and salt. In constructing the dietary it will be convenient to remember that a pint of milk, one egg, a quarter of a pound of fish, and two ounces of meat contain altogether 72 gm. of protein. Allowing for the protein in bread and vegetables it will be seen that the amount of nitrogen in this diet errs rather on the side of liberality. It will, however, serve as a rough guide. He can be helped by saline diuretics and unirritating preparations of iron. He will do all the better if his medical man realises that many of the methods recommended in the treatment of this disease are impotent where not actually harmful.

W. L. B

CHRONIC INTERSTITIAL NEPHRITIS

The causes of chronic interstitial nephritis or granular kidney are essentially the same as those of arterio-sclerosis; in some cases the stress falls upon the large arteries and the kidneys suffer secondarily, in others the kidneys suffer first, necessitating a rise of blood pressure to effect due circulation through them, with consequent detriment to the arteries. Treatment must be directed in the first instance to removing the cause where possible; thus gout, alcohol, lead and syphilis are the special artery destroyers. But there are also poisons absorbed from the alimentary tract, such as the diamines formed from the putrefaction of proteins, which have been shown to have a definitely pressor effect, and must in time damage both arteries and kidneys.

In some cases no cause can be found, but there is a family tendency to the condition, as if, in Sir William Osler's phrase, "inferior rubber had been used in the tubing." Such patients may have lived exemplary, frugal, self-denying lives; not infrequently they have been the subjects of migraine in earlier days. I have seen some marked examples of this type in women. There is not so much to be done in the way of treatment here, for the mode of life calls for little alteration, and they do not stand restriction of diet well. But in the main, granular kidney is a typical disease of modern civilisation induced by rush and strain, over-eating and over-drinking, burning the candle at both ends.

General Prophylactic Measures.—The timely discovery of a trace of albumen and casts in the urine should act as a danger signal, enabling the brake to be applied before disaster occurs. But it is still more to the advantage of the patient if the condition is recognised while he is still in the stage of merely raised arterial tension, before organic changes have taken place. It can hardly be doubted that such a functional stage does occur, probably in every case. For its recognition we must rely on the sphygmomanometer in middle-aged patients who complain of shortness of breath on slight exertion, giddiness on rising quickly from a chair, frequent headaches, bilious attacks, epistaxis, difficulty in mental concentration, irritability or insomnia. For a patient with granular kidney complains of these effects of raised arterial tension; the large amount of limpid urine is usually a matter for pride rather than anxiety with him, and lumbar pain, despite the advertising vendor of patent remedies, is almost unknown.

In the full-blooded type of patient "full of coarse strength and butcher's meat" much may be done by regulating the diet and altering

the mode of life. Late hours, evening meetings in stuffy rooms, especially when accompanied by heated political discussions are to be condemned. In few conditions are both the dish of herbs and contentment more essential, or the stalled ox and strife more injurious.

Diet.—The bulk and number of the meals should be reduced; roasted meat must be partaken of sparingly, while soups, gravies and internal organs should be avoided altogether. On the other hand, fruits, green vegetables, farinaceous and non-nitrogenous foods may be taken freely. The salt added at table should be stopped, and in severe cases a salt free diet may be advisable for a time. If the pressure shows a continued tendency to rise, a few days' rest in bed on a milk diet is advisable. Soured milk can only be expected to be of service where there is definite evidence of intestinal intoxication. Coffee, tea and tobacco should be limited, and in certain cases excluded. Thus tobacco should be forbidden if it causes cardiac distress or pain; in my experience this is most likely to occur if mixtures containing Cavendish or Latakia are smoked. Alcohol is usually bad for such patients, except where the heart is weak and the appetite poor; then a small quantity may be allowed with food, but drinks between meals must become things of the past.

Baths may be a valuable adjunct to treatment. A cold bath is inadvisable, but a warm bath either at night or on rising will be beneficial. In the latter instance the warmth may be gradually reduced by running in some cold water. The advisability of Nauheim baths (the materials for which can now be readily obtained) is not so certain. It is not that their efficacy in lowering pressure is doubtful; the objection is that they do so by direct vaso-dilatation. They may be followed by rather alarming faintness. The Turkish bath may suit some cases very well as long as there is no cardiac distress in the hot room and a sufficient time is allowed for cooling and rest. Plombières douches are recommended where there is suspicion of intestinal intoxication. An annual course of balneological treatment is often very useful; the regulation of the life, freedom from worry and the change of surroundings are probably of more importance than the chemical ingredients of the water. The kidneys will respond to increased ingestion of fluids readily enough, but there is no proof that the flushing-out treatment is beneficial even here. Von Noorden considers that moderate restriction of fluids, say to 1½ litres or rather more than 2½ pints, does not diminish nitrogenous excretion and spares the heart.

Climatic Treatment is of value as in other forms of chronic nephritis (*q. v.*).

Aperients.—It is of the greatest importance that the bowels should be kept freely open, to eliminate both the toxins from the body and the pressor diamines formed in the bowel. Sulphates are specially indicated for this purpose, since they are used by the body to combine with putrefactive substances and thus render them innocuous. As sodium sulphate is more readily absorbed into the circulation than the more aperient magnesium sulphate, preference should be given to the former, since this combination is effected in the liver. A weekly dose of calomel or mercury pill may also help, but as in other forms of nephritis, there is risk of mercurialism if they are given more frequently.

Exercise in the open air, without strain, and not carried to the point of affecting the pulse or respiration is a great help in these early cases. If modern conditions of life are largely responsible for granular kidney, they have also evolved a most useful prophylactic measure by popularising golf, the best form of exercise for those liable to these degenerative changes. But rest after meals should not be curtailed. In many cases the response to such simple, physiological methods of treatment has been remarkably good, enabling patients to continue to lead a useful and active life.

Depressor Remedies.—The great objection to lowering arterial tension by drugs is that we do not know what is the correct pressure for any particular degree of interstitial nephritis. Certainly some elevation of pressure is necessary, as it is essentially a conservative process which should not be directly antagonised by vaso-dilators. Like a rise of temperature in an infection, the rise of pressure in granular kidney is a symptom. In all pathological attempts at repair, however, the body may overshoot the mark, and it may then become as imperative to lower the pressure as to treat hyperpyrexia. In such a case those drugs should be chosen which have a slow and prolonged action. The fall of pressure produced by amyl nitrite is too brief to be registered by the manometer. Nitro-glycerine only lowers pressure for forty minutes. Erythrol tetranitrate in ½ gr. doses, on the other hand, will produce a fall lasting six hours. The chief objection to its use is its tendency to cause severe headache in some patients. Mannitol also produces a prolonged effect. Oliver recommends the tabloids Sodii Nitrit. Co. prepared for him by Burroughs and Wellcome which have the following composition—

Sodii Nitrit. gr. ss
Erythrol Tetranitrit. gr. ¼
Mannitol Nitrit. gr. ¼
Ammon. Hippurate gr. i.

One of these tabloids may be taken twice or thrice a day. If given for lengthy periods they

should be omitted for a few days or a week in each month.

Potassium iodide falls into a different category. It is doubtful whether it has any special action on the calibre of the blood-vessels. But it has a distinct effect on the elimination of poisons such as lead, mercury and the toxin of syphilis. The undoubted benefit from its use in some cases of granular kidney with high pressure is probably due to its eliminative action on the various and vaguer toxins here concerned, so that it is not merely attacking a symptom but may be striking at the root of the mischief.

Guipsine has also been recommended in such cases and may be administered in pills containing three quarters of a grain. As, however, it acts through the vasomotor system, it seems to me to be open to the same objections as the nitrites.

Venesection finds warm advocates, but it is to be looked upon rather as an aid in an emergency arising from high pressure than as suitable for general treatment. But such success as the old-fashioned routine "blood letting" achieved was presumably in cases of this nature. And after all it is only imitating nature's way of dealing with them by epistaxis.

Patients who are inclined to be nervous about their condition should not be told the reading of the manometer, and they should never read the index themselves, as this may easily send the pressure up 10 mm. But if they are told that there is an improvement, the pressure will probably fall at once, showing the effect of mental agitation. Indeed the introduction of the sphygmomanometer has produced a new form of neurosis, in which the patient is constantly thinking about his pressure, and for this it is to be feared the medical profession is responsible.

The albuminuria of granular kidney is slight in amount and unimportant in its effect. It calls for no treatment.

Treatment of Complications.—In so far as the change in the kidneys has occurred in chronic interstitial nephritis it is permanent, and we can only resist the encroachments of the disease step by step with the aid of the physiological principles already laid down. But special symptoms may arise from time to time, some of which will call for treatment.

Dyspnœa is due to one of two things, uræmic "asthma" or failing heart. In the former case the patient will probably be drowsy and the gums may be spongy while the pulse will probably remain regular. There is likely to be sweating and the volume of the urine will be diminished. It must be treated as described under uræmia, by free purgation, diminished nitrogen intake, large doses of sodium bicarbonate and perhaps venesection. The use of stimulating diuretics is less open to objection in this form of nephritis, and the following mixture may be ordered every four hours—

Diuretin gr. x
Potass. Tart. gr. xx
Spirit. Juniperi ♏. xxx
Inf. Scoparii ad ℥ i.

Or 2 gr. of theocin sodium-acetate may be given every six hours.

If the dyspnœa is due to the heart failing behind the excessive pressure there will probably be an irregular pulse, a more marked reduction in the secretion of urine and œdema of the legs. This last symptom only occurs in granular kidney when the heart begins to fail. Complete rest is indicated, and 5 min. of Tr. Strophanthus with 5 gr. of potassium iodide should be given every four hours. If this is not enough, oxygen should be inhaled to spare the work of the right heart, and venesection may be tried. Nitrites given on the plan already described may help to tide over the difficulty. Although morphia is rightly considered risky in diseases of the kidney, there is no doubt that it may afford great relief in cardiac distress and may justifiably be given a cautious trial. But cardiac symptoms show an important downward step in a case of granular kidney. Henceforward we are on the horns of a dilemma; if the pressure is allowed to become too high there is danger either of cerebral hæmorrhage or cardiac failure, while if it is lowered too much the patient feels miserable and depressed, and the urinary excretion becomes inadequate, so that toxins accumulate in the tissues.

Epistaxis is a safety-valve which should not be checked too soon, *hœmaturia* is of a similar character and calls for no special treatment. *Retinitis* cannot be treated. The treatment of a complicating *pleurisy* or *pericarditis* must be on the ordinary lines. *Digestive disorders* are due to a mild chronic uræmia and should be treated by restricting the nitrogen in the diet and by free purgation. *Insomnia* may yield to diffusible stimulants such as 20 min. each of Sp. Æth. Nitrosi, Sp. Æth. Co. and Sp. Ammon. Aromat. well diluted. Another remedy is 20 gr. each of bromide and chloral-amide. S. West considers Cannabis Indica the best hypnotic in this disease. But it may be necessary to resort to morphia to break the sequence of restless nights which are wearing the patient out. W. L. B.

URÆMIA

Broadly speaking, the most acute or fulminating forms of uræmia will manifest nervous

symptoms, while the subacute will display respiratory disturbances, and chronic uræmia will lead to gastro-intestinal troubles. This distinction is more apparent than real, for the respiratory and gastric symptoms are central in origin, being due to the action of a toxin on the medulla. Diarrhœa, on the other hand, is often due to "albuminuric" ulceration of the intestines, and, therefore, in my opinion, is better not regarded as a manifestation of uræmia. Again, in both the respiratory and gastric types, purely nervous symptoms will probably occur as the case gets worse. From the point of view of treatment, the important thing is to recognise the uræmic character of such manifestations.

Uræmia may occur either in the course of acute or chronic nephritis. A child with previously healthy kidneys may develop uræmia within forty-eight hours of the onset of scarlatinal nephritis, and a man may become uræmic who has been known to be the subject of granular kidney for years.

The treatment of uræmia is unsatisfactory, as the underlying cause is usually an incurable and progressive lesion. Indeed, only in acute nephritis can we expect to do more than stave off the fatal issue for a short time. When uræmia depends on an acute congestive nephritis the engorgement of the kidneys may be relieved by dry cupping of the loins. Four cups should be applied. For the relief of vomiting I have had most success with the administration of 1 min. of Tr. Iodi and ½ min. of carbolic acid in 1 dr. of water every quarter of an hour for three or four hours.

Apart from this, the primary indication in the treatment of uræmia is the rapid elimination of the accumulating toxins in every possible way.

1. **Elimination by the Bowel.**—Of all the routes available, the bowel is the simplest and one of the most effective to bring into action. For this reason we should never be in a hurry to check the diarrhœa which may be present, as it is nature's effort to eliminate toxins. The irritating effect of these toxins is probably responsible for the ulceration which may be revealed at the post-mortem examination. Von Noorden has shown that 8 gm. of nitrogen can be eliminated by the bowel, while not more than 3 gm. can be got rid of by the skin. Such drastic means as croton oil, elaterium and gamboge are seldom to be recommended; they are too irritant for an already irritated intestine. Five gr. of calomel followed by ½ oz. of magnesium sulphate, should be tried, or 1 dr. of Pulv. Jalapæ Co. In milder cases of chronic uræmia the compound colocynth pill every other night may be sufficient. If not, 1 oz. of Mist. Sennæ Co. should be given without delay.

2. **Elimination by the Kidney.**—The limitations of diuretics in nephritis apply with even greater force to uræmia, for the condition is a manifestation of the failure of the kidney to do its work. Very little can be expected, therefore, from diuretics in uræmia. In parenchymatous nephritis the stimulating diuretics, such as caffeine, are liable to do harm by irritation of the kidney. (For discussion of the action of diuretics in nephritis, see article on *Chronic Nephritis.*)

3. **Elimination by the Skin.**—This method of treatment is open to the following objections: (1) Very little nitrogen can be got rid of through the skin compared with the amount that can be eliminated by the bowel. (2) Physiological rest for the kidney is not secured by giving it a highly concentrated urine to deal with, for defective adjustment of the kidney to varying concentration of the urine is a prominent feature of nephritis. (3) Diaphoresis is an exhausting process and depressing to the heart. (4) The withdrawal of so much fluid without a corresponding removal of organic solids must increase the concentration of the toxins in the circulation.

If, therefore, it is decided to employ diaphoretic measures in uræmia, it should be, after fully weighing these objections, as applied to the particular case. It has been urged in support of this method of treatment that, after a hot-air bath, the patient may be actually covered over with small crystals. These crystals, however, in the main do not consist of urea, but of sodium chloride. And here we have the clue to the kind of case in which diaphoresis may be of service, namely, that in which there is a defect in the elimination of sodium chloride with consequent œdema. For the retained salt increases the osmotic pressure of the tissues, and this tends to increase œdema and to diminish excretion. The elimination of salt by the skin may, therefore, be of indirect service by breaking a vicious circle. The vapour bath or hot pack may also be used, but they are more trying to the heart than the hot-air bath. None of these procedures should be continued for more than a quarter of an hour after sweating has begun, a careful watch must be kept on the pulse, and the bath or pack stopped at once if there is any sign of collapse; stimulants should be at hand. Pilocarpin occasionally produces a great improvement, but is a dangerous method of bringing about diaphoresis. It is profoundly atonic in its effect on the heart. Moreover, as it causes outpouring of other secretions besides that of sweat, a drowsy patient may be drowned in his own pulmonary and bronchial exudate. It is given as the nitrate in doses of $\frac{1}{16}$ gr. hypodermically, or $\frac{1}{8}$ gr. by the mouth. It should not be repeated within four hours.

After diaphoresis, the temperature may fall dangerously low in spite of hot bottles and blankets. The temporary improvement which is produced sometimes by this treatment may be, in my opinion, purchased too dearly at the expense of the subsequent exhaustion.

4. Elimination by Bleeding.—A spontaneous epistaxis has been noticed to avert an attack of uræmia, and there can be little doubt that venesection is the most rapid method of removing some of the toxins. This can be combined advantageously with infusion with normal salt solution. In this way a larger amount of blood can be abstracted and the toxins diluted. As the vascular tension is usually high the volume of infused fluid should be less than that of the blood removed. Thus 30 oz. of blood can be removed and 20 oz. of saline infused. If the blood pressure remains high after venesection, say over 170 mm., vaso-dilators, such as nitroglycerin, $\frac{1}{100}$ gr., may be given every four hours. Removal of cerebro-spinal fluid by lumbar puncture is recommended by some authorities, and is a rational procedure, since the toxins must presumably be present there in considerable amount.

Inhalations of oxygen have been recommended, but any benefit derived is probably due to its cardiac effect. As Lewis and Barcroft have shown that uræmic asthma is due to an acidosis large doses of alkalis should be given as in diabetic air-hunger. Inhalations of chloroform are probably the best treatment for uræmic convulsions. Osler strongly recommends morphine, considering it indispensable for the restlessness and delirium. I have certainly known it to do good in the extreme restlessness and dyspnœa of chronic uræmia in consecutive nephritis, but I am inclined to agree with Burney Yeo that, if it be freely used for this purpose, the restlessness of uræmia may be relieved by the repose of death.

W. L. B.

MOVABLE KIDNEY

Before discussing the treatment of this condition, it is necessary to define exactly what one means by the term "movable kidney." To many the term implies a kidney the lower pole of which can be palpated during inspiration. This is certainly an incorrect view to hold, for careful examination reveals the fact that the lower pole of the kidney can be felt in a very large number of spare individuals under these circumstances. Abnormal mobility may be said to exist in a kidney which has definitely prolapsed so that half to three-quarters or more of its surface can be palpated, or in one which has undergone rotation around a horizontal axis, without undergoing any prolapse. Such a kidney will not be palpable at all, but must be included in the classification, as it is in this form that the most acute symptoms, those known by the name of Dietl's crises, occur. A large majority of the patients who develop movable kidney are women. In many cases the kidney produces no symptoms at all, and is only discovered during the routine examination of the patient. In these cases the best treatment is to say nothing about the kidney to the patient, but to make a note of its existence, and possibly to inform the friends or relatives of the patient of the condition, at the same time pointing out that the kidney is giving rise to no trouble. I cannot too strongly protest against the opinion which has been advanced in certain quarters that almost any conceivable disease, from insanity to appendicitis, may be caused by undue renal mobility.

Treatment is only demanded in cases of movable kidney which are giving rise to symptoms, and these may be either acute or chronic.

Acute Cases.—To these the name of Dietl's crises has been applied. They are produced by strangulation of the renal vessels owing to rotation of the kidney, which may also become incarcerated in its abnormal position.

Treatment.—The patient must be put to bed, and warmth should be applied to the affected side by means of hot fomentations. The pain may be so severe that a hypodermic injection of morphia may be required, $\frac{1}{4}$ to $\frac{1}{2}$ gr. being administered, after the diagnosis has been definitely made. A purge may also be given, as the peristaltic movement of the gut thus induced may rectify the position of the affected kidney. Under this treatment the attack usually passes off within a few hours. Should it persist longer an anæsthetic may be given, and an attempt made to rectify the faulty position of the kidney by bimanual manipulation. This is sometimes successful, but in a few cases an operation may be necessary to release the kidney. At the operation the kidney should be fixed to the lumbar parietes after the faulty position has been reduced. Owing to the greatly congested and swollen condition of the organ at the time, this operation cannot always be successfully performed, in which case it should be fixed later when things have quieted down.

Chronic Cases.—It is the exception rather than the rule for a movable kidney to cause trouble, but it will be well to refer briefly to the various symptoms that may be properly referred to this condition.

1. *Pain.*—This is commonly a dragging pain in the back, most noticeable in the posterior renal angle. It may also be met with anteriorly in the hypochondrium, exceptionally it is

complained of extending down the back of the thigh and leg.

2. Dyspeptic symptoms are fairly common.

3. Frequency of micturition often occurs.

4. More serious symptoms are referable to the production of a hydronephrosis, which may become infected, and thus give rise to pyonephrosis.

5. Occasionally there may be produced dilatation of the stomach, due to the formation of adhesions in connection with a movable kidney.

Treatment may be either operative or palliative.

The following points serve as indications for operative treatment.

1. Cases in which acute symptoms such as pain with hæmaturia and vomiting occur.

2. Cases in which there is evidence of pathological changes in the kidney as a result of its mobility. Such are hydronephrosis, intermittent albuminuria, and the presence of casts in the urine.

3. Cases in which the kidney is mechanically causing pathological changes in other viscera, *e. g.* dilatation of the stomach, or duodenum, and occasionally jaundice.

4. Cases in which chronic dragging pain exists, and which cannot be relieved by the palliative treatment to be presently described.

A certain degree of neurasthenia, which exists very commonly in these patients, does not contra-indicate operation, but if an operation be performed simply for the neurasthenic condition in the absence of any of the special indications for operation mentioned above, the results will be disappointing and the recommendation of operative treatment cannot be justified on any grounds. I have seen several patients who have been so treated without the smallest benefit to their neurasthenic conditions, but with the additional disadvantage of having a scar in which to feel pain and discomfort.

Palliative Treatment.—In a large number, perhaps the majority, of patients in whom a movable kidney is giving rise to symptoms the wearing of a suitable kidney truss or special corset will, as a rule, prove quite effective. Many of the patients have lost flesh recently and are in a poor state of health. There is accordingly an excessive reaction to sensory impressions which they would disregard if in a better state of health. In such a patient a rest cure should be obtained under the most favourable conditions, and after this a belt or corset ordered. The nutrition of the patient must be improved by giving extra milk, cod-liver oil and malt, if these can be well taken. Sufferers from movable kidney are almost always very constipated, so that careful attention to the bowels will be required.

A word or two is necessary on the important question of the choice of a truss or corset. Many of the articles advertised for this purpose are of no use whatever, and may do more harm than good by allowing the kidney to descend and then fixing it in this abnormal position. Most careful fitting is necessary, and a good deal of patience must be exercised on the part of the patient, doctor and the truss-maker if the instrument is to be a success. The instrument made by Ernst is very efficient, and as it is light it can, as a rule, be worn without much discomfort by the patient. The truss need only be worn during the day and should be applied by the patient before getting up in the morning. She must adjust it while in the recumbent position, preferably with the pelvis raised on a pillow. The loin should previously have been grasped by the fingers and thumb, to make sure that the kidney is in its proper position before the truss is applied.

As a result of wearing an adequate truss or corset the expectation is that the symptoms will be relieved. Experience shows that after a year or two, during which the truss has been worn, it may be possible to relinquish it without recurrence of symptoms. In the case of men who have to lead an active life, and in whom movable kidney is often due to trauma, it is probably better to advise operation at once, rather than to rely on a kidney truss.

For the details of the operative technique the reader is referred to works on operative surgery.

C. M. H. H.

KIDNEY DISEASE IN PREGNANCY

Introduction.—Under this heading will be discussed the treatment of the Kidney of Pregnancy, Eclampsia and Pyelitis during Pregnancy.

It must be remembered that the kidneys may show pathological changes, and albumen may be present in the urine during pregnancy in several other conditions, such as pernicious vomiting, icterus gravis, and hydatidiform mole, but in these conditions the kidney lesions are of secondary importance and it would be out of place to consider their treatment here.

Two great groups of kidney disease in pregnancy can be distinguished.

Group I, in which the patient has had no previous kidney trouble, and in which the disease is entirely due to the pregnancy. These are cases of true toxæmia.

Group II, in which the patient has suffered from previous kidney symptoms which are made worse by the patient being pregnant. The pregnancy is an accidental complication of an old-standing disease.

In dealing with a case of kidney disease in pregnancy, therefore, it is necessary clearly to

distinguish between these two groups. Failure to do so has led to much confusion and divergence of opinion upon the subject, and to errors in prognosis.

The distinction may be made by a consideration of the following points. In some cases, however, it is extremely difficult to make the distinction, and of course it is possible that a true toxæmia may be superimposed upon a case of old kidney disease so that the two conditions may exist together in the same case.

In *Group I* no history of scarlet fever or diphtheria is often obtainable, nor of any previous symptoms of kidney disease; there are no evidences of cardiovascular change; the blood pressure is usually increased, but it falls quickly after delivery; the patient is usually a primipara; the symptoms appear towards the latter months of pregnancy; the œdema is most marked about the legs and vulva; the eyes show no changes except intense œdema and partial detachment of the retina, retinal hæmorrhages are not common, and these changes totally disappear after the patient recovers; the urine is markedly diminished in amount and may contain much albumen (principally paraglobulin), some casts, and a diminished amount of chlorides—further, it may contain acetone and diacetic acid; the total nitrogen excretion is lessened, the percentage of urea may be lowered, and there may be a rise in the amount of the ammonium salts and undetermined nitrogen; the alkalinity of the blood is less.

In *Group II* there is usually a history of scarlet fever or of diphtheria and of a previous attack of kidney disease; there are evidences of cardiovascular changes, the arteries may be thickened, the heart hypertrophied and the blood pressure increased; the patient is usually a multipara; the symptoms appear early in the pregnancy; the œdema is most marked about the legs and face; the eyes may show evidence of albuminuric retinitis; the urine before the pregnancy may have been increased in amount, and it contains albumen and epithelial casts, but no acetone or diacetic acid. The cerebrospinal fluid may be shown to contain urea.

The Treatment of Group I

(*The Kidney of Pregnancy—Eclampsia*)

The present-day treatment of this group of kidney diseases in pregnancy is based upon the fact that they are regarded as examples of a true toxæmia.

The toxæmic theory may be stated briefly thus. It supposes that in health the waste products or toxic substances are eliminated either directly by the alimentary canal, the kidneys, the sweat glands, and the lungs, or by transformation within the body into non-toxic substances chiefly by the liver. During normal pregnancy the amount of waste products is increased by those derived from the ovum. Two factors, therefore, come into play, the amount of waste products, and their elimination. Should the amount of these waste products be much increased, or the overworked functions of the excretory organs break down, then a condition of toxæmia or auto-intoxication results.

The toxæmic theory is not a proved fact, but it is now generally accepted, although the toxin or toxins have not yet been isolated or demonstrated and their nature and mode of action remains unknown. The known facts point to the presence of a toxin circulating in the blood of the pregnant woman, and further that this toxin is derived from the epiblastic covering of the chorionic villi, and it is upon this view that our treatment is based.

The toxæmia may manifest itself clinically in various ways. The boundary line between physiological and pathological processes is ill-defined in pregnancy. It is now believed that many of the minor ailments of pregnancy are toxic in nature, *i. e.* pruritus, salivation and vomiting. These do not manifest kidney changes and so will not be considered here. More severe manifestations of toxæmia are the kidney of pregnancy, eclampsia, pernicious vomiting and acute yellow atrophy; these show kidney changes, but in all except the kidney of pregnancy and eclampsia the changes are subsidiary and so the treatment of these two only is considered here.

1. **The Kidney of Pregnancy.**—A patient suffering from this condition usually complains of symptoms during the latter months of pregnancy. She may complain of vomiting, headache, dimness of vision and swelling of the legs, and on examination the urine contains albumen.

Prophylactic Treatment.—Every pregnant woman, and especially primigravidæ, should have the urine examined regularly twice a month during the latter half of pregnancy. The urine is to be tested for albumen. Some authorities attach great importance to the percentage of urea, but it is doubtful whether this carries the significance attributed to it. Only when we also know the total nitrogen and ammonia nitrogen can we get satisfactory chemical evidence of the approach of toxæmia. (See also article on *Chronic Nephritis.*) The patient should be warned to notify her doctor if she has headache, œdema or dimness of vision, and if she passes only small amounts of urine.

Should these symptoms be present or the urine be diminished in amount and contain albumen then treatment must be at once begun.

Curative.—The indication is to get rid of the

toxin which is supposed to be present in the mother's blood. This can be eliminated by the kidneys, bowels and skin.

The patient is placed in bed because there a more accurate knowledge of the intake and output can be obtained. The diet must be light, nitrogenous food is to be avoided in order to save the extra work of the liver and kidneys. At first she may be allowed milk, cocoa, bread and butter, custard, eggs and fish. She must not have alcohol, rich food, soups, meat extract, any meat or vegetable.

The effect of this diet upon the symptoms must be watched, and in more severe cases the diet must consist only of milk—two quarts in the twenty-four hours—and the patient encouraged to drink as much barley-water and imperial drink as possible with the object of flushing the kidneys. Some simple diuretic such as Pot. Acetate and Spiritus Ætheris Nitrosi may be given.

In order to eliminate the toxin by the bowel a free evacuation should be obtained daily—for this magnesium sulphate is indicated, because of the fluid motions it causes, by which means it is possible that some of the maternal toxins may be disposed of.

To combat the acidosis found in toxæmic cases, glucose 5 per cent. may be given. A pleasant way is to add to it the juice of a lemon, which is known as glucose lemonade; if the patient feels too sick to retain by the mouth it may be given per rectum and also as much saline as possible.

Under this treatment there is usually a rapid improvement, the œdema subsides and the urine increases in quantity and contains less albumen. An index to the degree of improvement is given by a urine chart—showing the percentage of albumen, amount of urea and amount of urine passed daily.

Should the symptoms persist and there be no improvement in the condition of the urine—the urine become scanty, contain more albumen (preferably estimated by Aufrecht's method), and the amount of urea diminish, then the pregnancy should be terminated in order to free the mother's body of the source of toxin. The mother's interests mainly are to be considered, for the fœtus often dies in utero—and by terminating the pregnancy there is less danger of the onset of ante-partum hæmorrhage and eclampsia. This is done by the introduction of bougies between the membranes and the uterine wall. Contractions appear in from twelve to seventy-two hours, and when the cervix is fully dilated, the forceps should be applied, provided the vertex presents and is well in the pelvic cavity; otherwise version should be performed and the child allowed to be born slowly and not immediately delivered. All manipulations must be performed gently for fear of causing stimuli which may in their turn give rise to eclamptic convulsions. As little chloroform as possible should be given, for lesions similar to those of eclampsia have been found in the liver in cases of prolonged chloroform anæsthesia. To avoid this the anæsthesia may be obtained by the extra dural sacral—not spinal—injection of stovain, or by the administration of ether by the open method.

2. **Treatment of Eclampsia.**—*Prophylactic.*—Prophylactic measures are of the greatest importance. They have been already considered under the treatment of the *Kidney of Pregnancy*, in which condition, indeed, our chief aim is to guard against the onset of eclampsia.

Should the symptoms not improve or should the patient become progressively worse, then the onset of eclampsia must be regarded as imminent.

Usually clear indications of its onset are given by the persistence of the headache; an increase in the amount of œdema; the presence of eye changes such as dimness of vision, flashes of light in front of the eyes and even sudden blindness; by epigastric pain, vomiting, giddiness and muscular twitchings. The urine becomes scanty in amount, the albumen much increased while the urea is less.

By the employment of precautionary measures the liability to eclampsia is much diminished, but we are not able to claim that it can be absolutely prevented. Eclampsia may still occur even after all the symptoms have subsided, and even with scarcely any warning. I know of a patient whose first symptom was sudden blindness before the appearance of albumen in the urine.

Curative Treatment.

1. *Medical.*—On account of our small knowledge as to the causation of eclampsia, our aims are in the main still empirical and symptomatic.

The treatment may be considered under the following heads—

(a) *The Treatment of the Fit Itself.*—The patient, if possible, should not be moved during the fit, but allowed to rest where she lies in order to obviate all unnecessary handling and stimulation.

A gag must be placed between her teeth. If no real gag is at hand then a spoon or some similar firm object with a handkerchief wrapped round it will answer the purpose. This is done in order to prevent the patient from biting her tongue during the convulsion.

The head must be turned on to one side in order to prevent blood and saliva from entering the air passages with the risk of suffocation immediately, or of septic broncho-pneumonia at a later date.

The patient must be gently restrained from

injuring herself, and a pillow be placed beneath her head.

The clothing must be loosened in order to allow as much air entry as possible.

The question of the administration of chloroform or morphia during the fit is discussed later.

(b) *The Prevention of the Recurrence of the Fit.*—The patient must be put to bed, her clothing being gently removed and no irritating material placed next her skin. The bedroom itself should be in the quietest part of the building, the blinds should be drawn down and no bright light or sudden noise be allowed to penetrate into the room. No one should be allowed to see the patient other than the doctor or nurse. All unnecessary manipulation must be avoided, such as vaginal examination or the use of catheter or enema.

The diet must be the same as for a severe case of the "Kidney of Pregnancy." If the patient be unconscious the feeding should be done by means of the nasal tube.

Various anæsthetic or sedative drugs are given to prevent the explosions of nerve energy which originate the convulsion.

Of such drugs we must consider—

Morphia.—This drug is simple of administration and is pleasanter to both patient and doctor than chloroform; it tends to retard protein metabolism and so may help by diminishing the formation of toxins; it allays restlessness; it diminishes arterial tension and has a marked effect upon the fits. But it tends to weaken the uterine contractions and so delays labour.

It is to be recommended in ante- and postpartum cases of eclampsia, and especially if there is no sign of coma and the pulse is full and bounding.

It is best given in full doses of $\frac{1}{2}$ gr. subcutaneously, together with atropin sulphate $\frac{1}{100}$ gr., on account of its depressant action upon the respiratory centre. This dose may be repeated if necessary until 2 gr. of the morphia have been administered.

Chloroform.—The drug acts quickly, is rapidly eliminated and can be administered to patients who are unable to swallow. During the actual convulsion it is not of much value as the patient is scarcely breathing.

But sometimes it has no apparent influence in controlling recurrence of the convulsions, and its prolonged administration is contraindicated not only because it is troublesome to give, but because it may set up lesions of the liver similar to those found in eclampsia.

It may be administered in two ways. The first is to give it at intervals to ward off an oncoming convulsion, watch being kept for signs of this, such as widening of the pupil and fibrillary tremors of the muscles of the face. The drawback to this method is the length of time taken up and the risk of causing hepatic lesions. The second is to give it when vaginal or intrauterine manipulations are necessary. It is generally given in intrapartum eclampsia to control the convulsion, and for obstetric manipulations.

Chloral Hydrate and Bromide of Potassium.—These may be given as substitutes for chloroform or morphia, or in combination with small doses of morphia.

If given by the mouth full doses should be administered, such as 30 gr. of chloral and 15 gr. of bromide every hour until four doses have been taken. Should the patient be unconscious they may be given in double the doses by the rectum combined with starch mucilage. But should there be no good effect at the end of the four doses their administration is better discontinued.

Lumbar Narcosis.—Spinal anæsthesia as well as lumbar puncture followed by the removal of some of the cerebro-spinal fluid have proved ineffectual in controlling the occurrence of the fits.

Veratrum viride has been recommended for its action as a vaso-dilator and diuretic, but on the other hand it is a cardiac depressant and its use is by no means free from risk. The dosage is 15 min. every half hour until the pulse-rate falls to sixty beats a minute. It may be given as veratone, 1 c.c. intramuscular injection if the patient be unconscious.

Thyreoid Extract.—Extracts of the gland may be given, as according to some an insufficiency of the thyreoid internal secretion is regarded as the cause of eclampsia. Whether this be so or not is open to doubt, and where relief appears to have followed its use it may be due to its vaso-dilator and diuretic action.

Pituitary extract has also been recommended, but so far the results are not sufficient for us to draw any definite conclusions.

(c) *The Elimination and Dilution of the Toxins.*—The toxins may be eliminated by the bowel, by the skin, and by the kidneys.

(i) *By the Bowel.*—The special drugs which are indicated for this purpose are castor oil, jalap and magnesium sulphate. If the patient is unconscious 2 min. of croton oil should be given in a small piece of butter in order to protect the buccal mucous membrane. These drugs are of value in that they not only cause a free evacuation from the bowel and so dispose of some of the toxins, but they also tend to lower the increased blood pressure.

(ii) *By the Skin.*—It is usually recommended to make the patient perspire by the free use of hot packs or the vapour bath, and by drinking large quantities of fluid, or the administration of saline per rectum.

Of these methods the drinking of large quantities of fluid where possible is the best, for the use of the others entails a good deal of movement and manipulation, and these may bring on the convulsion. Further, as Bumm has pointed out, it would appear as if sweating in some cases has caused stronger convulsions, deeper coma and a higher degree of fever, and it is not clear that the supposed eclampsia toxin leaves the body with the sweat. It may be that sweating makes it more concentrated.

Pilocarpin should certainly not be given on account of its action upon the bronchial glands and the risk of pulmonary œdema.

If the temperature reach as high as 105° F. it should be reduced by the tepid bath at a temperature of 70° to 80° F. until the rectal temperature falls 2° to 3°. Profuse sweating follows, and the temperature will continue to fall.

(iii) *By the Kidneys.*—Large quantities of bland fluid rather than active diuretics should be given by the mouth; barley-water, water, imperial drinks are all suitable. To counteract acidosis, glucose 5 per cent. may also be given, preferably with some lemon-juice added. Subcutaneous saline should be given, but this is contra-indicated in the presence of fits or if the patient is restless. The saline should then be administered per rectum in large quantities, or intravenously. It is usual to add a drachm of sodium acetate to a pint of the saline in order to increase the alkalinity of the blood, which is diminished in eclampsia from the normal 0·202 gm. per cent. to 0·153.

The saline is to be recommended, for it dilutes the toxin, causes diaphoresis, and some hours later acts as a diuretic.

(iv) *By venesection.*—The toxins may be lessened and the blood pressure lowered by the removal of some of the patient's blood from the median basilic vein. This may be done as a preliminary, also, to the intravenous *infusion of saline,* in order not to raise the blood pressure. The removal of blood is to be recommended if the patient is cyanosed, shows signs of œdema of the lungs and has a full bounding pulse with raised blood pressure. It is contra-indicated if the patient is anæmic, feeble and has a low blood pressure. From 10 oz. to 1 pint of blood should be removed according to the condition of the patient. Not seldom it has been noted that the fits immediately stop and the coma dissipates. Lichtenstein records that one venesection in 54 per cent. of cases was followed by cessation of the fits.

Zweifel has recently shown the blood is more concentrated in eclampsia, and he goes on to state that it "is difficult by means of therapeutic statistics to speak of proof; but most of my colleagues will hold it of importance if from my actual experience I affirm that the removal of blood has in no case done harm, and that it has very often appeared to save life."

Further it must be remembered that the coma may be deepened owing to CO_2 poisoning, for during the convulsions the air entry is interfered with, and at all times there is some obstruction from the presence of mucus. Removal of some of the blood and the administration of oxygen are to be recommended if the patient is cyanosed. Artificial respiration is necessary in some cases.

Serum Treatment.—This is recommended on the supposition that the toxins of pregnancy call out ferments in the normal patient's blood, which are able to counteract them. Should these ferments not be produced in sufficient quantity then the toxins are unchecked and a condition of toxæmia will result.

These ferments may be artificially supplied by the administration of human serum from the blood of normal pregnant women, and also it is claimed from non-pregnant women, or from the horse.

Good results are recorded by Fieux and Gui from serum administration given in doses of 15 to 25 c.c. either subcutaneously or by the mouth, in cases of hyperemesis gravidarum, which, like eclampsia, is regarded as a manifestation of the toxæmia of pregnancy. It has been recommended on this analogy, but up to the present evidence in its favour is inconclusive.

2. *Obstetrical Treatment.*—There are two entirely and strongly opposed views as to this. On the one hand, it is claimed that no obstetrical manipulations are necessary unless the woman is in labour or prolonged medical treatment fails; the other view is that on the occurrence of a fit the pregnancy must be terminated at once.

The former view is based upon the statements that the convulsions are not due to the labour, they occur apart from labour and the labour pains do not stimulate them, and that according to Herman they continue in 57 per cent. of cases after labour. Therefore the main thing is to treat the fits by medical measures and not to hasten delivery.

The latter view is based upon the supposition that the condition is due to toxæmia and that the toxin is derived from the ovum. Therefore the toxin should be removed by the removal of the ovum, and as there is still much toxin within the maternal system even after the expulsion of the cause convulsions may still follow, so that the medical treatment must be continued even after the delivery. If we rely upon statistics of the proportion of cases which have no more convulsions after the birth, it is 66 per cent. according to Zweifel; he also finds a maternal mortality of 28·5 per cent. by the

expectant treatment as against 11·25 under active obstetrical measures.

Most investigators now favour the second view. In the absence of a fit treatment should be by the medical measures already discussed, but if the symptoms become worse, or if a single fit occur, then prompt delivery should follow. In our methods of hastening delivery we consider the interests of the mother first, for the child is often premature, diseased and malformed.

If the Patient is not in Labour.—The cervix should be dilated by metal dilators until it will admit a Champetier de Ribes' bag, and when it is fully or almost fully dilated the labour should be terminated by the forceps or by version.

If the cervix be extremely tough and undilatable then either vaginal or abdominal Cæsarean section should be performed, if a competent operator be available and the conditions are suitable. Abdominal Cæsarean section is preferable, especially if the child is large and the vagina small, but the vaginal method may be practised if the child is small —before the twenty-seventh week—and the vagina large.

The anæsthetic to be used for these manipulations should be ether by the open method, provided that there is no evidence of pulmonary œdema, but if this is present chloroform should be used in as small a quantity as possible.

If the Patient is in Labour the treatment is much simpler. If the cervix is not fully dilated it should be dilated by the digital method. If the head presents and is not too high apply the forceps; if this instrument is contra-indicated perform version and bring down a leg.

During the management of the third stage some degree of bleeding may be beneficial where the patient is cyanosed and has a full pulse.

After the delivery the medical measures against the toxæmia must be continued. Special attention must be paid to the increased liability of infection locally, to septicæmia, and to the signs of the onset of puerperal insanity.

The question may arise as to future pregnancies. To this we answer that the attacks are seldom repeated, especially if the attack has occurred in a primapara. The patient must, however, be warned that there is some risk.

3. *Surgical Treatment.—Decapsulation of the Kidneys* has been recommended in cases of total or almost total suppression of urine in order to relieve the venous stagnation within the kidneys. At present there is not sufficient proof of this line of treatment to allow us to judge of its merits, but any such procedure is attended by many and severe manipulations, and, it must be remembered, the risk of infection is greater in eclamptic patients.

The Treatment of Group II

(*Pregnancy with Chronic Nephritis*)

The treatment of chronic nephritis is considered separately in the present work (see p. 333). Only the following points from the obstetrical point of view, therefore, need to be added.

It may be supposed that the previously damaged kidneys have been able to perform their function satisfactorily so long as no added strain was put upon them. When the patient becomes pregnant this added strain is supplied, for now not only the maternal but the fœtal products of metabolism have to be eliminated; they are unable to do so and consequently a breakdown in their function and an increase in the amount of permanent kidney lesion result.

If this view of the pathology of the condition be correct, then it will be readily understood that should palliative measures not be attended by rapid improvement, the pregnancy should be terminated. Expulsion of the ovum is usually followed by marked improvement in the symptoms. Further, the life of the child is so precarious in this condition that our treatment must be primarily in the interests of the mother.

Should the medical man be asked to give his opinion as to the advisability of marriage, he must remember he has no right to forbid it. He should point out the facts to the individuals concerned and explain the risks.

The patient is usually worse in a succeeding pregnancy, and the symptoms earlier in their appearance.

Sometimes, however, patients who are known to be the subjects of chronic nephritis have passed through successive pregnancies and survived.

The Treatment of Pyelitis during Pregnancy.—This can no longer be regarded as a disease special to pregnancy. It is well known to occur in other conditions; it occurs quite commonly in young children, and it may do so also in men. The treatment of this condition is considered on p. 350; here we are mainly concerned with its relation to pregnancy and to the puerperium.

Medical Treatment.—The patient should be placed in bed. It is usual to direct her to lie upon the opposite side to that affected in order to drain the pelvis of the affected kidney. This is based upon the view that the pregnant uterus is compressing the ureter—usually the right—against the brim of the pelvis. That this view is really correct is open to doubt. In many cases the right ureter shows a dilatation from this point upwards, but cases have occurred in which the dilatation has been along the whole length of the ureter from its insertion into the bladder. At any rate such a position is good

in that the diseased kidney is uppermost and is therefore less pressed upon.

The symptoms certainly subside more rapidly if the patient is confined to bed.

The diet should consist of milk, cocoa, custard, bread and milk and small quantities of eggs and fish in order not to overwork the damaged kidney structure.

The kidneys should be flushed through with large quantities of barley-water or imperial drink. Urinary antiseptics such as urotropin or helmitol should be given by the mouth. Urotropin is best given in the powder form, 5 gr. with 20 to 30 gr. of acid sodium phosphate three times daily.

The bowels must be regulated, especially as constipation or colic so often precede and accompany the attack.

Serum and vaccine treatment have so far proved disappointing on the whole. The commonest causal organism is a coliform bacillus. The reason why an anti-coli serum fails may lie in the fact that the Bacillus coli group contains so many organisms which vary slightly in their biochemical reactions and the serum may not be suitable for the particular case, and further it is open to doubt if the Bacillus coli really does produce any antibody. Vaccines must, of course, be autogenous. The dosage is from 10 millions increased up to 100 millions repeated with forty-eight-hour intervals.

A sensitised vaccine is recommended also, in which case the dose begins with 100 millions and is repeated at twenty-four-hour intervals until three doses have been given.

The results of vaccine treatment are not conclusive. It is difficult to be sure that any observed improvement is really due to the vaccine, for the improvement occurs suddenly very often without any such treatment or before the course of vaccines has had time to be completed. This much may be said, that the symptoms do appear to be kept in abeyance as long as vaccines are administered, although it is interesting to note that the organisms may still be found in the urine sometimes for many months afterwards.

Operative Procedures.—In the majority of cases medical treatment alone is sufficient, a marked improvement taking place within about ten days.

In cases where no such improvement is manifested, Stoeckel has recommended irrigation of the renal pelvis. There are obvious objections to such a procedure, nor is it probable that any benefit would follow, because in severe cases not only is the kidney pelvis affected but the kidney substance contains many small abscesses. Two fatal cases seen by the writer both showed these lesions at the post-mortem examination.

If, after ten days' treatment upon the lines already indicated, the patient is no better, the temperature persists and the pulse-rate is increasing, the question of operative interference arises. The case is complicated by the pregnancy, for any operation upon the kidney is likely to be followed by abortion. It is better to drain the kidney by diminishing the bulk of the uterus by terminating the pregnancy. This is most conveniently done by the introduction of bougies between the membranes and the uterine wall.

But such a procedure should not be undertaken lightly. It is very seldom necessary, and does not always succeed in bringing about any improvement in the symptoms.

Finally, we may remark as to preventive treatment that the condition may occur during the puerperium, therefore all unnecessary use of the catheter should be guarded against.

J. D. B.

ESTIMATION OF THE RENAL ADEQUACY

Unfortunately it must be admitted that there is at present no really satisfactory method of estimating the functional power of the kidneys, and yet, with the exception of the work of the heart, there is hardly a question on whose answer so much of importance to life depends. In the present very short epitome I must confine myself simply to those tests which seem to me to be of practical interest.

What are the Clinical Signs of Renal Inadequacy.—These are agreed on—the patient's skin is loose and dry, his complexion dull yellow, conjunctivæ dull and somewhat œdematous, tongue dry and somewhat glazed, he complains of constant frontal headaches, and may admit a certain amount of polyuria, his urine may be of low specific gravity and show a cloud or haze of albumen. This is all that can be obtained—trivial symptoms one may say, and yet an operation on the urinogenital tract (or elsewhere) in such a patient will almost certainly be fatal.

Tests of Renal Adequacy.—Here we have to decide on (1) the adequacy of both kidneys, (2) that of either kidney separately, and of these the second is the question which will more frequently present itself for decision. It is now generally admitted that all attempts to separate the urine coming from either ureter *in the bladder* and to collect it separately are entirely fallacious and should be discarded. Thus at present the only satisfactory method of examining the urine from either kidney is by catheterisation of the ureters by ureteral catheters passed under the direct view of the cystoscope. It is clear that this method can only be used by the expert, further, that it requires continued exposure as the catheters

must be left in the ureters for at least two hours (no anæsthetic is necessary).

Radiography.—Reliable radiographs of the kidney area will at any rate show us the outline of a normal kidney and may prove the presence of a normal kidney free from calculi on the opposite side to a diseased kidney.

Pyelography.—Vœlcker first attempted the injection of the pelvis of the kidney with a 2–5 per cent. solution of collargol, a soluble organic salt of silver, which casts an X-Ray shadow. Thomson Walker uses a 10–20 per cent. solution of collargol; of this solution he injects about 20 cc. from an all-glass syringe held from six inches to one foot above the level of the body into each ureteric catheter (the catheters are also opaque to X-Rays). On the first appearance of symptoms of discomfort in the renal regions the injection is stopped and an X-Ray photo taken. By this means the permeability of the ureter and the size, position, etc., of the pelvis of each kidney may be defined.

Injection of Phloridzin.—Ten milligrams of phloridzin are injected subcutaneously into the buttocks; sugar should appear in the urine of a healthy person in fifteen minutes—occasionally up to thirty—after the injection. The amount of glycosuria is usually 1–2 gm. of glucose, and it should have passed off in from 2–2½ hours. In urinary obstruction there is diminished elimination of sugar and in badly damaged kidneys sugar may be absent.

Injection of Methylene Blue.—Fifteen minims of a 5 per cent. aqueous sterilised solution of methylene blue are injected into the buttock. The methylene blue is excreted first as a chromogen, and later as methylene blue itself. The chromogen (which turns into methylene blue when boiled with acetic acid) should appear in the urine in from 15–20 minutes, soon after this time the excretion of unaltered methylene blue should begin; it should be at its maximum in from 4–5 hours, and should have disappeared in from 40–50 hours. This test cannot be relied on, for in acute or subacute nephritis the rate of methylene blue excretion is entirely unaffected.

Injection of Phenol-sulphone-phthalein.—Six milligrams are injected hypodermically, the urine from the ureteric catheters is allowed to drop into a 25 per cent. solution of potash; as soon as the drug begins to be excreted a pink colour is obtained which gradually deepens into red. The amount of the drug excreted is estimated by a colorimeter. "In normal cases the colouring matter is said to appear in from five to ten minutes, 40–60 per cent. of the drug is excreted in the first hour, 20–25 per cent. in the second, and 60–85 per cent. in the first two hours."—(Thomson Walker.)

Injection of Indigo Carmine.—0·16 gm. of indigo carmine is dissolved in sterilised water and injected hypodermically; in about ten minutes the urine is coloured, and then passes through various stages of green to blue, the greatest amount being excreted in about an hour after injection; the quantity can be roughly estimated by the eye or more accurately by a colorimeter.

"Delay in the appearance and a feeble staining of the urine are signs of disease."—(Thomson Walker.)

Examination of the Urine of the Healthy Kidney.—A ureteric catheter can be passed into the pelvis of the (presumably) healthy kidney and the urine collected for 2–2½ hours and carefully examined. In the middle of the process a cup of hot tea or other diuretic may be given. After the collection, urotropin and a diuretic should be given, and the patient should remain in bed for thirty-six hours. This method is obviously not free from risks.

It will be readily seen from the foregoing very brief statement that the various methods of estimating renal adequacy are highly complicated, both from the chemical and surgical points of view, and it must be admitted that it is unsafe to rely on any one of them—in a doubtful case it is important to have the results of all of them before the surgeon for final decision. J. K. M.

DISTENSION OF THE PELVIS OF THE KIDNEY

Non-suppurative Hydronephrosis.—While it must be admitted that treatment of non-suppurative distension of the kidney must be confined to surgical measures only, and these of a somewhat technical character, it is of practical interest to note that much progress has been made from those by-no-means far-off days when the hydronephrotic kidney was hurriedly removed or perhaps tapped again and again through the loin.

More recently the pelvis was drained through the loin, and as it came to be admitted that the mobility of the kidney was at times an indirect cause, nephropexy or fixation of the kidney was performed.

At the present time surgery is directed towards the preservation of the kidney by discovering and treating the cause of the distension at as early a stage as possible.

As to the *causes of hydronephrosis* we must remember that in a considerable proportion of cases examined post-mortem no cause is discoverable (in fourteen out of nineteen cases, Herringham), in the remainder obstruction of some kind is found and this most frequently is advanced malignant disease of the female pelvic organs.

It is well known that hydronephrosis may be *temporary and intermittent* or *permanent*.

Temporary Hydronephrosis.—In all such cases expert surgical advice should be sought, for here the cause may be (1) kinking or even twisting of the ureter of a mobile kidney, which comes to lie in loose tissue instead of fairly firm retroperitoneal fat. Here fixation of the kidney should provide a cure.

(2) Intermittent valvular obstructions by calculi, folds or even small growths of the calices of the kidney—towards the renal orifice of the ureter. Here recognition of the cause provides the proper line of treatment: stones and growths are removed by horizontal incisions through the pelvis of the kidney, and in those cases where there is complete obstruction to the ureter a lateral or end-to-end anastomosis of the ureter to some other part of the pelvis should be undertaken.

Permanent Hydronephrosis.—This is most frequently due to complete obstruction of a ureter by (1) (and most frequently) malignant disease—usually in the pelvis. Here treatment will most probably only consist in establishing a renal fistula in the loin in the hope of preserving the still functional cortex—although the extent and progress of the disease may make even this undesirable; it is to be remembered that in some early cases of pelvic carcinoma the ureter has been successfully cleared from the growth.

(2) By calculi obstructing the ureter in any part of its course. Here it is worth remembering that (*a*) the degree of the obstruction by no means corresponds to the size of the calculus—rather the reverse; (*b*) that such calculi cannot be excluded by radiography even in the hands of the most expert; (*c*) the recently adopted injection of a ureter with collargol (an organic compound of silver opaque to X-rays) will show the position of an obstruction to the ureter in any part of its length and clear up the diagnosis of a doubtful shadow, as well as prove the presence of a normal ureter on the opposite side.

Calculous obstruction is obviously to be dealt with by removal of the cause, suture of the ureter or pelvis of the kidney, with artificial enlargement of the structure, or anastomosis if necessary.

(3) Due to aberrant branches of the renal artery—a by-no-means uncommon cause. In this condition the lower aberrant branches appear to pass from the aorta over the ureter, thus actually constricting it (Mayo), while aberrant branches to the upper pole of the kidney would appear to cause a torsion of the whole organ. These aberrant branches can be readily felt through a lumbar incision, clamped and ligatured—usually with a most satisfactory result.

(4) Due to ureteral strictures and much rarer developmental causes.

Thus the treatment of hydronephrosis is essentially surgical; yet, nevertheless, successful *surgical* treatment rests on the early diagnosis of the practitioner, for the sooner it is diagnosed and the cause removed the better the chance of saving the kidney. In early cases the history may help the practitioner, but alterations in the *quantity* of urine are delusive. There is no pain unless there is a moving calculus or superadded septic infection.

If the practitioner is in any doubt as to the presence of *any* enlargement in the renal region he will do well at once to obtain the evidence (*a*) of X-rays, (*b*) of cystoscopy and collargol intra-ureteral injection by an expert, while an estimation of the efficiency of the sound kidney by pyelography, phloridzin and methylene blue tests should be conducted as a matter of routine.

J. K. M.

GENERAL INFECTIVE CONDITIONS OF THE KIDNEY

Pyogenic Infections

Pyogenic infections of the kidney may best be considered in the following divisions—

(*a*) **Pyelitis.**—Here the suppurative changes are usually confined completely to the pelvis of the kidney.

(*b*) **Pyelonephritis.** — Here the infection has certainly attacked the pelvis of the kidney, but in addition it has also spread into the cortex and there caused diffuse inflammation and multiple abscesses; on the other hand, in some cases it is equally reasonable to suppose that the infection has spread from the cortex to the pelvis.

(*c*) **Pyonephrosis.** — Here obstruction to the ureter, usually by a calculus, is superadded to the original infection, the infective process rapidly destroys the kidney substance, which is meanwhile being distended by pressure, and unless the obstruction is relieved at an early stage, the kidney is soon changed into a large thin-walled bag of pus and the suppuration spreads into the perinephric tissues.

Source and Cause of Infection

1. **Embolic.**—There is no doubt that organisms can be brought into the kidney by the circulation; in health there is little doubt that large quantities of organisms are excreted by the kidneys, some alive, but most of them either dead or with their toxicity greatly reduced: in depressed conditions of the general organism or of the circulation; we know that B. coli is able to pass in large numbers from the intestine into the intestinal blood and lymph vessels, and in this way it reaches the kidney.

2. **Ascending Infection** from the bladder along the ureter. This is probably a far rarer

source than was once supposed, it may occasionally be the cause of pyelitis in young female children, but it is far more common in the ascending pyelonephritis of long-infected bladders and in pyonephrosis.

3. **Lymph Infection.**—This is probably by no means uncommon in pyelitis, for the lymph vessels of the pelvis of the kidney have free communication with the lymph vessels of the colon. (Thomson Walker produced a pyelitis in a kidney whose ureter was ligatured, by injecting colon bacilli into the bladder.) The cause of infection is almost always the B. coli in some form, more rarely the staphylococcus, still more rarely streptococci, proteus or the pneumococcus.

Pyelitis

It is well to insist at the outset on three points: (1) pyelitis is essentially a febrile disease; not only so, but the fever is not infrequently the only symptom discovered. The presence of fever will usually distinguish pyelitis from cystitis (scf. cystitis). (2) The amount of pus in the urine is not large, usually only a cloud or a faint haze, while in many very acute cases, and in children, there is only the condition known as bacteriuria—a faint haze consisting of myriads of coliform organisms and a few pus cells. (3) It is common in children, uncommon in adults, and common in later life.

Pyelitis in Children.—Pyelitis is common in children under twelve months, the infant becomes suddenly ill and has a rigor (a rigor in an infant is, according to many, almost pathognomonic of this infection), the temperature rises to 103°–104° F., falls within twelve hours and rises again. The child is very evidently ill, there is a good deal of twitching, but, on the other hand, vomiting is rare; female infants are usually exclusively affected. The amount of pus in the urine is microscopic, but there are swarms of coliform bacteria. The urine is in all cases strongly acid, and in some cases it produces a yellowish staining of the diapers.

Once the diagnosis is made the prognosis is invariably good and the treatment simple. Most observers are agreed that the first line of treatment should be to alkalinise the urine. This can readily be accomplished in infants under one year by giving 5 gr. of citrate of potash in syrup every two hours, at the same time giving, if possible, double the amount of fluid usually taken, *e. g.* by giving boiled water between the milk feeds. The patients are usually very thirsty and take fluids readily.

After one year 2–5 gr. of bicarbonate of soda can be added to the citrate of potash according to the age of the patient. In the majority of cases the temperature falls in between two to five days of this treatment, but the urine will be found still to contain B. coli, and it is wise to continue the treatment for fourteen days after the temperature has become normal. Curiously enough in some few cases—I do not know of any bacteriological distinction—the alkaline treatment fails, and here urotropin should be given in doses of 1½–2½ gr. every four hours up to one and a half years of age, 2 gr. up to two years, 3 gr. up to three years, etc. Here the same precautions with regard to continuance of treatment should be taken. Some have suggested instillations into the renal pelvis of argyrol or silver nitrate. I can only say that such treatment appears to me to be highly dangerous, seeing that both kidneys are nearly always affected. Moreover, for the past twelve years I have never been called in to see a case of pyelitis by my medical colleagues at Paddington Green; as they always found simple medicinal treatment to be entirely satisfactory.

Pyelitis in Adults.—This is, as I have already said, uncommon, though not so uncommon in the later years of life; it is usually of a rather different type.

1. *Mild Cases.*—As in the case of children the attack begins suddenly, usually with a rigor, and the temperature is of the same remittent type, but here acute bladder symptoms and intense pain are quite frequent and strangury occurs in 6 per cent. of the cases. The average case lasts from ten to fourteen days despite treatment. The urine is hazy and swarms with B. coli, it has usually a very characteristic and foul odour of stale fish, and it is not infrequently alkaline in reaction.

2. *Acute Cases.*—The acute cases begin very often with a sharp attack of pain closely resembling renal colic, there are a succession of rigors very often, and the blood-count shows a marked leucocytosis, hæmaturia is occasionally found early in these cases; in the worst of all, drowsiness, changing to coma and death, ends the scene. It is to be noted that relapses are quite common in adults, and that the acute and dangerous type of case is the rule in the aged. Both kidneys are usually affected.

Treatment.—The patient should be kept strictly in bed and kept warm. Milk diet should be given with fish or eggs, red meats and alcohol should be avoided. "Malt-Glidine" added to milk or Bengers' Food will be found to give the patient an admirable and refreshing fillip. The kidneys should be flushed with unirritating fluids, that is to say, the total amount of fluids taken in the twenty-four hours should be raised to 4–6 pints if possible. The fluids given should be barley water, Imperial drink, Evian, Vichy or Contrexeville water and the like, and the fluids

given should be constantly varied. Free action of the bowels is obviously desirable, and is to be maintained by senna, cascara or calomel, if necessary by salines. The reaction of the urine is a most important factor in medical treatment, for it is now well known that the so-called urinary "antiseptics" have little if any action in the presence of alkaline urine (cf. *Urinary Antiseptics*, Part II). Thus, if the reaction is alkaline, ammonium benzoate 10–15 gr., should be given every third hour until the reaction is altered, acid sodium phosphate 30 gr. to each dose may also be tried, but ammonium benzoate generally gives better results. Once the reaction becomes acid, urotropin 10–15 gr., helmitol or tetralin (10–30 gr.) should be given every three hours.

Vaccine Treatment is a somewhat controversial ground. Many do not believe in its efficacy, others—amongst them myself—have had excellent results. Out of sixteen cases in adults treated by me with autogenous vaccines the average duration of symptoms was six days after the first injection in fourteen of the sixteen; at the end of fourteen days the urine was free from coli in two. Colon bacilli were still present in both these cases (the vaccine had had no apparent effect on the symptoms); in one of these unsuccessful cases there was a bad relapse. There has been no relapse, so far as I am aware, in the others. All are agreed that the vaccine, if used, must be autogenous, for the actual strain of organism varies probably in each case, and the name of the coli group is indeed legion. I have been in the habit of beginning with 5 millions and continuing every three days, increasing by 5 millions up to 50 millions if necessary. It has been recommended to keep the patient lying on either side alternately, in order to "drain the pelvis." It seems very improbable that a mere change in position can in any way improve on Nature's arrangements. For the same reasons as in pyelitis of children, irrigation of the pelvis of both kidneys by surgical methods appears to me to be wholly inadmissible.

Pyelitis in Pregnancy.—This is dealt with more fully under the *Kidney of Pregnancy*.

J. K. M.

PYONEPHROSIS

The condition may be described as a purulent collection within the kidney which distends the kidney and forms an actual tumour.

Here, as in the case of pyelitis, infection may be either (1) from the blood stream, or (2) ascending; and it will be admitted here that ascending infection is by far the most common. It is usually due to infection of a kidney irritated by the presence of calculi which may or may not subsequently block the ureter.

In some rare cases there may be a mixed infection as the result of an original tuberculous tumour. There is usually hectic fever and there is no large quantity of pus in the urine.

It would, however, be a mistake to consider that the temperature is always raised. It has fallen to the lot of most surgeons to meet cases where there is an enormous quantity of foul pus in the kidney without any elevation of temperature, and here again an entire absence of leucocytosis is often observed, even where pus is pent up.

A distended kidney does *not* form a *fluctuating* tumour, for its peripheral as well as perinephric tissue is usually much thickened by inflammation.

Treatment of Pyonephrosis.—While depending primarily on the condition of the remaining kidney—and every care must be taken to investigate its condition by radiography and ureteral catheterisation with collargol—if the disease is unilateral, the proper treatment would be to remove the kidney. In acute cases of great distention, the kidney should be very freely opened first and drained. It has to be remembered that in over 50 per cent. of such cases a discharging sinus remains and the treatment is unsatisfactory. In such cases the remaining kidney should be removed at a second operation, the ureter ligatured as low down as possible and divided.

J. K. M.

PYELONEPHRITIS

An "*aseptic*" *form* is described as due to acute retention, chronic obstruction, or the excretion of irritants; it is characterised by thirst, dull lumbar pain, dry tongue, frontal headache, and polyuria—in fact all the usual symptoms of renal insufficiency; treatment in this form should be directed to removal of the cause, and otherwise does not differ from that of the other forms to be described. Pyelonephritis is, however, in the vast majority of cases, suppurative, and is usually caused by an ascending infection by B. coli from the bladder, although rarely there may be a unilateral infection from the blood stream.

Acute Infective Pyelonephritis.—Here, in addition to a suppurative pyelitis, the kidney substance is riddled with multiple minute abscesses, or round cell infiltrations; for practical purposes it may be considered as the finale of chronic septic cystitis with or without obstruction such as prostatic enlargement or stricture, or as the results of surgical interference in a chronic septic urinary tract. In such cases it is usually considered, rightly or wrongly, to be the result of a chill; and it generally begins with a rigor, the temperature may be raised or subnormal throughout, the patient is drowsy and

complains of backache and thirst, the tongue is dry and glazed, and there is nausea and constipation. He lies on his back with his legs drawn up, the abdomen is rigid and distended, there is tenderness over the kidneys, and sometimes one kidney may be felt enlarged. He passes a considerable quantity of urine containing pus, most of which probably comes from a septic cystitis. Soon the drowsiness increases, vomiting, hiccough and muttering delirium set in, convulsions are rare, suppression of urine now occurs, the drowsiness changes to coma, and within twenty-four hours death ends the hopeless scene. Where a cure can hardly be said to exist it will be admitted that prevention is the better part, and thus it behoves the sufferer from urinary obstruction or cystitis to seek and obtain adequate treatment at an early stage before it is yet too late, while it is equally important for the surgeon to abstain from brilliant operative measures in debilitated subjects with chronic septic cystitis with obstruction and content himself with draining the bladder first.

Treatment.—The only possible line of treatment that can be adopted once acute ascending pyelonephritis has set in, is to attempt to keep up or to restore the excretory work of the kidneys. As a first measure dry cupping should be applied to the loins, followed by turpentine stupes and a hot pack, the bowels should be made to act freely and at once by a drastic purge, such as Pulv. Jalapæ 30 gr., Colocynth 10 gr., Calomel 7 gr., or Croton Oil 2 min., followed by turpentine enemata. In the hope of directly stimulating the renal secretion Pilocarpine $\frac{1}{100}$ gr. may be injected hypodermically, but pituitary extract with atropine probably produces a better result (one vaporole of extract (B. W. & Co.), and $\frac{1}{100}$ gr. atropine every four hours). For the same reason the amount of fluid in the tissues must be increased; it will be found very difficult to get the patient to take large quantities of fluid, but if possible fluids should be given as in the case of pyelitis.

One to one and a half pints of normal saline should be gradually run into the tissues every six hours. Five per cent. solution of glucose, one pint every eight hours, is a hypertonic solution, and is probably far better (the necessary quantity of glucose can be readily obtained in tabloid form and added to boiled water). The arrangement of letting the fluid run through the needle into the tissues by gravity from a Thermos flask is, I suppose, now too well known to need description. Two and a half per cent. glucose solution may be injected into a vein; but intravenous injection has no advantage over slow injection into the tissues; indeed, the latter method is in every way preferable. If the solution is not absorbed into the tissues, as shown by the disappearance of the local swelling, there is obviously no reason to repeat the injection. Surgical interference in the acute condition appears to me inadmissible, and likely only to precipitate the fatal end.

The prognosis of this terrible condition is most grave. If the kidneys can once be got to secrete freely recovery may ensue, and then the question of surgical treatment by draining the bladder or even draining the pelvis of one kidney with a large tube, if there is any reason to believe that one kidney is more affected than the other, may be considered. On the other hand once complete suppression has set in, the condition is almost hopeless.

Chronic Pyelonephritis.—This condition is most usually caused by an ascending infection from a septic bladder, and most often is the insidious early part of the disease which terminates as acute pyelonephritis. Its characteristic symptom is the presence of large amounts of pus in the urine; the urine is usually acid, but ammoniacal urine is not unknown. Bacilluria is very rare, but, of course, organisms can be cultivated from the urine, and these are usually coliform; there are often symptoms of vesical irritation.

A thick layer of creamy pus in an acid urine should at once indicate that the kidneys are probably affected. In such a case the symptoms of renal insufficiency—thirst, dry tongue and skin, chronic frontal headache, polyuria and occasional lumbar pain—should be first inquired into. Next the excretory capacity of the kidneys should be examined (see *Renal Adequacy*). If the kidneys are known to be adequate it is imperative that the cause should be attacked at once and thoroughly treated, this including a full radioscopic examination of the whole urinogenital tract, examination of the urethra and prostate, cystoscopic examination, and examination of the orifices of the ureters. It is to be remembered that the disease is almost always bilateral (85 per cent.), still proof may be obtained that it is unilateral. The cause of the septic cystitis, whether due to stone, enlarged prostate or simply coli infection, should now be dealt with, and it is probably the wisest course to drain the bladder first if there has been chronic obstruction. If the pyelonephritis is proved to be unilateral, and the remaining kidney adequate, the diseased kidney should be explored and drained. If there be stones in the pelvis or ureter these are removed and the case will probably do admirably. Pyelonephritis caused by stones in both kidneys presents a difficult problem. If the kidneys are adequate, an attempt should be made to remove the stones on what appears to be the worst side, and when this has healed

up the other side should be dealt with. If the kidneys are inadequate, on the other hand, no operative procedures on the kidneys are advisable until, if possible, their secretory power is improved.

It is imperative to insist that no medicinal treatment should be undertaken and continued in the early stages of chronic pyelonephritis in the absence of a complete examination of the urinary tract by a competent surgeon. No change in the condition can or ought to be expected from the continued empirical use of drugs unless the original cause has been found and dealt with.

As *adjuncts* to surgical treatment urotropin, tetramine, hetraline or helmitol 5 gr. every four hours may be given if the urine is acid, ammonium benzoate 10 gr. if the urine is alkaline. Simple diuretics may be given freely, the amount of fluids taken should be regularly increased so as to flush out the kidneys, and the amount of proteins taken may well be curtailed. Minute doses of calomel $\frac{1}{20}-\frac{1}{6}$ gr. three times a day for a week at a time are strongly recommended by some. The patient should be specially told to avoid the risk of a chill or a wetting, and the seriousness of his condition should be insisted on. In many cases vaccine treatment in conjunction with the rest shows good results; the vaccine should in all cases be autogenous. One to two millions should be given for the first dose and repeated in four to five days, rising rapidly from 10 to 100 millions, 150 millions may then be given for six doses with a week's interval, and then 200 millions for six to twelve doses with the same intervals. But it must be admitted such treatment is long and tedious.

One last word—Medicinal treatment of chronic pyuria without a thorough examination of the whole urinary tract by every means at the surgeon's disposal is merely trifling with human life. J. K. M.

LARDACEOUS DISEASE

The connection between lardaceous degeneration in the liver, spleen and kidneys and prolonged suppuration is well known. Treatment of suppuration should be prompt, and as soon as albuminuria is discovered in a chronic suppurating case the cause of the suppuration should, if possible, be removed.

The various forms of surgical treatment recently advocated, which vary from opening up sinuses to the removal of the entire large intestine, belong more particularly to surgery.

It is worth nothing that when suppuration has ceased the lardaceous changes disappear first in the liver, next in the spleen and, last of all, in the kidney. J. K. M.

SYPHILIS OF THE KIDNEY

"It is impossible to deny but difficult to prove the existence of chronic nephritis due to acquired syphilis."—(Herringham.)

There is a general feeling that all forms of nephritis may be met with in syphilis, but some are sceptical whether they are actually due to the spirochæte or are merely associated with the disease.

Gummatous changes independent of diffuse infiltrations are extremely rare. Old sclerotic changes in the kidney are known, but cannot be definitely proved to be due to syphilis.

Nephritis in the Secondary Period.—The kidney is affected in 3 per cent. of cases according to Petersen. An acute parenchymatous nephritis occurs which is indistinguishable from scarlatinal nephritis with one exception, that is to say, that enormous quantities of albumen may be present but the amount of urine is not lessened in the same degree as in scarlatina. The renal permeability of methylene blue is either normal or raised. During the same period it will be remembered that albuminuria in small quantities is comparatively common.

Nephritis of the Tertiary Period.—Sclero-gummatous changes may occur in gummatous kidney. There is a form closely simulating chronic Bright's disease. A case of gummata of the kidney where actual signs of a renal tumour were present has been recorded by Sir A. Bowlby, and gummata may give attacks of pain similar to that of renal calculus.

With regard to treatment, most are agreed that mercurial treatment in syphilitic albuminuria is not very satisfactory and, in some cases, appears to aggravate the condition.

On the other hand, cases have occurred lately that have been successfully treated with Neosalvarsan. J. K. M.

TUBERCLE OF THE KIDNEY

In the study of infection of the kidney with the tubercle bacillus we find endless varieties of pathological conditions varying from the most minute collections of round-cell infiltrations to extensive miliary tubercles of the renal cortex and in extreme cases we may find the whole kidney enlarged and its cortex converted into bags of caseous material from which all cellular structure has long since vanished. Our attention is naturally directed to the study of what the primary cause of the disease may be, but here again we are beset with difficulties. In a great majority of cases it may be said to be due to an ascending infection of tubercle from the bladder either by the ureters or (more probably) by the lymph vessels, and tuberculous ulcers are to be found by the

cystoscope in the neighbourhood of the ureter. Tubercle of the kidney is, as has already been pointed out, a rare cause of pyonephrosis. Two other pathological facts remain to be mastered, and these are of intense importance—

1. There is practically no evidence of healed tubercle in the kidney in post-mortem examinations.

2. The second kidney is diseased in much more than half of all cases.

Having in view these statements one cannot fail to be pessimistic in considering the treatment of renal tuberculosis. The symptoms of the disease are, it will be remembered, pyuria with some lumbar pain, and considerable symptoms of vesical irritation, whether the bladder is affected or not, together with the recognition of the presence of the tubercle bacillus in the centrifugalised urine. The irritability of the bladder in some cases is most intense.

In a case presenting these symptoms the first essential in treatment is that the locality and extent of the tuberculous infection should be accurately diagnosed.

Cystoscopy should first be carefully undertaken, and despite its difficulty every attempt possible should be made by prolonged washing out of the bladder to obtain a satisfactory view. By this examination the surgeon ought to be able to decide on the presence or absence of tubercles in the base of the bladder, and their precise locality as well as the condition of the ureteric orifices.

If (1) there are no vesical tubercles the possibility of one kidney being affected is strengthened. (2) One ureteric orifice is normal and discharging healthy urine, whereas the other is red and "pouting" and discharging pus—the diagnosis is made still more certain. (3) In such a case, if possible, the diagnosis should be further confirmed by catheterisation of the ureters.

When tubercles are found in the bladder, on the other hand, the probability that both kidneys are affected is very strong. This can be further confirmed by an examination of the ureteric orifices and by catheterisation of the ureters.

In the fortunate and exceptional cases where tubercle is definitely proved to be confined to one kidney the removal of that kidney is most strongly indicated to avoid infection of the bladder, and possibly of the other kidney. It may be noted that Hurry Fenwick long ago called attention to this particular type of case and believed it to be due to lymphatic infection from a tuberculous epididymis to the kidney of the same side "missing out" the bladder—thus the history and condition of the epididymis may well be inquired into.

Where the bladder is affected and it is doubtful whether one or both kidneys are involved, unless there is clear evidence the diagnosis should be made that both kidneys are affected, and in the writer's opinion there is no room for surgical interference with the kidneys, and treatment—other than the draining of the bladder for the local conditions there present—should be entirely medical.

We are here faced with the question of tuberculin treatment—Herringham from a very wide experience of this condition advises it in all cases except those where removal of a kidney can be undertaken. He uses 0·00001 mg. of a human bacillary emulsion for the first dose, and injects twice weekly, increasing the dose with each injection 0·00001–0·00008, 0·00008–0·0001, 0·0001–0·0002. If the temperature rises more than one degree after an injection he misses the next injection due, and then at the same interval returns to the dose which originally caused the rise of temperature—several months of this vaccine treatment are recommended. At the same time there is no doubt that it will be well to give urotropin in the hope of its bactericidal effects, while belladonna and hyoscyamus will be required to diminish the distressing spasms; buchu tea, made by infusing an ounce of the leaves for five minutes in a pint of boiling water, may be given—up to half a tumblerful twice a day. All being said I must own to a profound feeling of pessimism in this terrible disease. In the mild cases confined to one kidney all is well. In the others life is one unutterable agony, and drainage of the bladder offers the only relief—and that a temporary one—to the patient's sufferings. J. K. M.

PERINEPHRITIS AND PERINEPHRITIC ABSCESS

Suppuration in the perinephric area is usually due to extension of inflammation from a pyonephrosis. Owing to the looseness of the tissue in this region it is usually an acute process and extends rapidly. In some cases, primary inflammation takes place in this area and a certain number of acute pneumococcal abscesses have occurred in this situation.

It may be observed that the hip is usually flexed, as is also the trunk towards the affected side and also that pain is complained of in the knee. In the point of view of diagnosis, these symptoms should be remembered.

Treatment consists in free exploration and drainage. In the acute stage belladonna and laudanum stupes with aspirin internally to relieve the pain. J. K. M.

HÆMATONEPHROSIS

This condition is very rare. It may be described as being the distension of the kidney

with blood, the cause being rupture of some main artery, usually near the pelvis. Aneurysm of one of the branches of the renal artery has been described as a cause. The possibility of this as an acute condition should be remembered.

In a case of the author's, a man was admitted to hospital cold and pulseless, complaining of pain in one loin. This condition of profound shock lasted for a day, and shortly after this a large renal tumour was discovered in the loin.

Skiagraphs showed a doubtful shadow in the ureter and, not unnaturally, the condition was diagnosed as one of hydronephrosis owing to the ureter being blocked by a calculus.

When the shock had completely passed off, the kidney was exposed and fortunately a semi-fluid tumour was first tapped with a small aspirating needle and pure blood drawn off; no stone was found in the ureter.

The opening of the kidney was secured and, at a later date, when coagulation was complete, the kidney was removed.

The case is worth attention for the preliminary aspiration and recognition of the case had not a little to do with the patient's recovery.

There was no hæmaturia in this case, but in a similar case recorded by Herringham there was profuse hæmaturia. J. K. M.

RENAL CALCULI

Renal calculi may be composed of oxalates, urates, uric acid, phosphates, cystin or of mixtures of these. It is necessary to consider some of the factors in the production of such calculi before discussing their rational treatment. The importance of infection as a factor in starting the aggregation of crystals into a calculus is well illustrated by the case of cystin stones. Cystinuria depends on a congenital metabolic defect in the breakdown of the sulphur-containing amino-acids of the tissues. In a family of cystinurics described by Garrod, only one member developed a stone and that one had bacilluria. In the treatment of any form of calculus, therefore, every effort must be made to render the urine aseptic by the methods described under pyelitis. (See also article on *Urinary Antiseptics*.) The only other suggestion as to prophylaxis against cystin calculi that has been made is based on the hypothesis that this endogenous cystin should become the taurin of the bile salts, and that its excretion as cystin is due to lack of cholalic acid with which it can conjugate. Cholalic acid may, therefore, help in preventing cystinuria. It can be given as tablets of colalin $\frac{1}{8}$ gr. to $\frac{1}{2}$ gr. three times daily before food. Restriction of the sulphur in the food has no effect, as this can be metabolised satisfactorily by the body. Alkalis help to dissolve cystin stones when formed, but cannot check the formation of fresh stones.

Benjamin Moore has shown that even in a uric acid stone the core is most frequently composed of calcium oxalate with some colloidal substance, possibly blood. In the prophylactic treatment of calculi it is therefore important to avoid oxaluria, as it may cause hæmaturia and thus provide a colloidal binding for a stone. Oxaluria may result from—

(1) Ingestion of food rich in oxalates, such as rhubarb, strawberries and spinach. It is doubtful whether any other article of food contains oxalates in sufficient quantity to produce symptoms. (2) From gastric or intestinal fermentation. This appears to take place under two opposite conditions of gastric secretion. If there is insufficient hydrochloric acid in the stomach, fermentation of the carbohydrates will occur there with the resulting formation of oxalates. If, on the other hand, there is hyperchlorhydria, it will probably be found, as pointed out by Mayo Robson and Cammidge, that oxaluria is associated with chronic pancreatitis. For the treatment of this condition see the article on *Diseases of the Pancreas*. It will follow, therefore, that in any case of oxaluria, careful attention must be paid to the state of the digestion. (3) In neurasthenic conditions, when oxaluria may occur in crises. At present, the method of production of the oxaluria in these cases is not understood, but treatment must be directed towards the nervous system.

Should deposit of oxalates occur, the recognised treatment is abstention from oxalate-containing foods and administration of magnesia, since the oxalates are more soluble in its presence. It has been shown that when the amount of CaO and MgO in the urine are about equal calcium oxalate remains in solution—probably owing to a formation of a soluble double salt. Peas should be taken when in season, as they are poor in oxalates and rich in magnesia. Potassium citrate is of service in two ways: (1) As a diuretic, diluting the urine; (2) by combining with the calcium it prevents the formation of calcium oxalate crystals. C. J. Martin showed that citrates form a non-ionisable double salt with calcium. Some observers prefer to employ lemon juice to sodium or potassium citrate. The drinking of lemon squash will tend to prevent oxaluria from eating strawberries.

An increase in urinary acidity will assist the solution of an oxalate calculus when it has once been formed, but the difficulty is that such increased acidity will promote deposit of uric acid crystals round it. Nevertheless R. Maguire has found that the administration of acid sodium phosphate (NaH_2PO_4) in doses of up to 1 oz. a day in 100 oz. of distilled water is effective in

diminishing the size of oxalate calculi. It is obviously important that there should be no ingestion of oxalates during this treatment, as the acid salt would facilitate their absorption.

The principal factors in the deposit of uric acid crystals in the urine is high acidity and high percentage. Acidity is at its height during fasting hours and is seldom a marked feature during digestion owing to the secretion of acid into the stomach. It is usually sufficient to give 20 grs. of potassium citrate night and morning to correct high acidity. There is one precaution which seems to me very important. If uric acid deposit has already occurred in the form of a calculus, rendering the urine alkaline would cause growth of the calculus by accretion of phosphates. The patient should, therefore, be told to put a piece of red litmus paper into the morning urine. If it turns blue, the drug must be diminished in amount until this just fails to occur. Fresh fruit such as pears, green figs, dates, oranges and grapes have a similar action in checking high acidity.

High percentage of uric acid may be absolute or relative, that is, the total output may be increased or the urine may be concentrated. Either would favour deposition. The former should be regulated by cutting off food rich in purins (see article on *Gout*), the latter by diluting the urine. Patients do not usually care to be ordered to drink plain water. Potash water is preferable to soda water because of the relative insolubility of the sodium salt. Lithia water formerly had a great reputation as a solvent of uric acid, but it is certain that it is ineffectual in the doses ordinarily taken, and that if sufficient lithia could be absorbed to be an effective solvent it would be poisonous. Really, it is the water which is the chief therapeutic agent. Certain waters such as those of Contrexéville have a high repute for washing out uric acid. It has been questioned, however, whether the treatment of Contrexéville does not increase the endogenous formation of uric acid; whether, in short, as Goodhart says, the gravel passed is not manufactured on the premises. But an alkaline mineral water will help to prevent deposit of gravel both by diluting the urine and by rendering it less acid. Few things are better than Evian water for this purpose.

Gee pointed out the extraordinary effect of whey in preventing uric acid deposits, and I can confirm this. It is not clear whether the effect is due to its diuretic action, but there is no doubt as to the fact. A breakfast cupful should be given twice or thrice a day.

Atophan is distinctly contra-indicated in uric acid gravel or calculi, because of its marked effect in increasing the output of uric acid.

Phosphates are always secondary in calculi, being deposited around some other substance and never forming the core. Normally phosphates are present in the urine as (1) acid phosphates of sodium and potassium; (2) earthy phosphates of calcium and magnesium. It is only the earthy phosphates which can form a deposit. The appearance of "knife rest" or "coffin-lid" crystals of ammonio-magnesium phosphate ("triple phosphate") is definite evidence of ammoniacal decomposition, probably due to a streptococcal or staphylococcal infection (for the treatment of this complication see *Pyelitis*). Apart from triple phosphates a phosphatic deposit is practically always due to diminished acidity of the urine and seldom to an absolute increase in the excretion of phosphates. If the urine is rendered acid, the deposit of phosphates will cease. Nitro-hydrochloric acid may be given for this purpose, and once the urine is made acid in this way it may be kept so by giving acid sodium phosphate in 30 gr. doses three times a day.

Sorebeer's diet has been tried in phosphaturia. Milk, eggs, fish and fruit, which contain a good deal of lime, are not allowed, while foods poor in lime, such as meat, potatoes and cereals are given. The phosphates are then excreted in a more soluble form. But as the phosphatic deposit depends either on ammoniacal decomposition or simple reduction of acidity, rather than on an absolute increase in the excretion of phosphates I have not tried it.

Renal calculi may produce both mechanical and septic results calling for treatment. In the former group are chronic renal pain with attacks of hæmaturia, renal colic and hydronephrosis; in the latter pyelitis, pyelonephritis, pyonephrosis and perinephric abscess. Only the first two come within the scope of this article.

Renal Pain.—If a renal calculus is diagnosed and this is confirmed by the X-rays, operative removal is indicated. The pain may be referred to the side opposite to that which contains the stone, so a skiagram must be taken of both kidneys. If the diagnosis is uncertain or operation is refused or postponed, the urine must be carefully examined for crystals and the treatment appropriate to the deposit continued as described under prophylaxis. A quiet life is advisable; horse exercise, railway journeys and violent exertion are well known to excite an attack of renal colic by starting the stone on its way down the ureter. For the symptomatic relief of pain, aspirin in 10 to 15 gr. doses, hot baths or antiphlogistine to the loins may be of service. Morphine should naturally be avoided in the treatment of chronic renal pain, on account of the danger of establishing a habit.

Renal Colic.—In the attack nothing is better than morphine tartrate $\frac{1}{6}-\frac{1}{4}$ gr. together with

atropine sulphate $\frac{1}{100}$ gr. hypodermically. The antispasmodic effect of the atropin aids the anodyne action of the morphine, and aids the onward passage of the stone. With morphine alone there is apt to be recurrence of the pain as the anodyne effect passes off. Tincture of belladonna 10 min. in 1 oz. of water should be given by the mouth every three or four hours until the pupils are dilated, the face flushed and the mouth dry. I have seen quite fair-sized stones passed *per vias naturales* under this treatment. Inhalations of chloroform may be necessary at the outset until the drugs have had time to act. Hot applications to the loins or the hot bath may help to relax the spasm. When under the influence of the atropin, barley water, lemonade or Evian water may be drunk freely to try and wash the stone along. Inversion of the patient is advised and a change of posture may certainly help to disengage the stone from the ureter. After the paroxysm is over the aid of the X-rays should again be invoked to locate the stone. W. L. B.

DISEASES OF THE PROSTATE

Acute Prostatitis.—This is usually met with in the second or third week of an acute gonorrhœa, though it may arise *de novo* as a result of a Bacillus coli septicæmia.

Fever is present and the prostate can be felt from the rectum swollen, hot and tender. After about three weeks the acute stage subsides and resolution occurs or the disease becomes chronic.

The patient should be persuaded to keep his bed, which he will usually do if there is much fever or if epididymitis is also present. Confinement to bed turns the scale in favour of the patient's bactericidal powers, and cannot be too strongly insisted upon. Prescribe diluent drinks and a non-irritating diet and prohibit alcohol. Local treatment must be of the gentlest description and consists of—

1. Antiseptic washes or injections for the *anterior* urethra only, such as potassium permanganate 1 in 3000 or albargin 1 in 2000.
2. The application of local heat by means of hot baths, hot-water bottles, fomentations.
3. Rectal suppositories containing iodex are of considerable value.

In very acute cases there will be complete retention of urine. If this will not yield to hot baths and a draught of 30 min. of laudanum a catheter should be passed as often as required. There need be no fear of infecting the bladder with the gonococcus by this procedure, which is preferable to suprapubic puncture.

The most serviceable drugs are those which relieve the pain and cause diaphoresis, aspirin being about the best. In severe cases morphia may be required. If chordée is very severe prescribe a bromide mixture, but in milder cases the chordée is at once relieved if the patient rises and passes water. If there is dysuria the best drug is some preparation of sandal oil.

Chronic Prostatitis.—This is usually the result of an acute prostatitis of venereal origin, but may be a very troublesome complaint of non-venereal hæmatogenous origin (Bacillus coli, streptococcus, staphylococcus), in those who ride or motor to excess or indulge in prolonged or too frequent sexual excitement.

The symptoms are protean and include intermittent gleet, the passage of threads in the urine, urethral irritation; pain in the urethra, perineum, rectum and back; sexual neurasthenia and impotence; chronic arthritis, lumbago and sciatica. It is surprising in how many cases of chronic joint trouble the source can be tracked to a latent bacterial focus in the prostate gland, and how quickly such disabling complaints melt away under suitable treatment applied to the organ.

The diagnosis can only be made by placing a finger in the rectum and squeezing out a drop of prostatic fluid, placing it under the microscope and detecting *pus cells* and *bacteria*.

It is one of the commonest diseases of modern life and tends to persist indefinitely unless treated on modern lines, and yet it is seldom recognised, as the method of diagnosis is not widely known.

The patient must get about and try and "keep fit," he should sleep in country air, feed up, take regular and sufficient exercise and school himself not to worry about his condition—a task in which he can and should be constantly and wisely aided by his doctor.

Great patience is required on the part of both, and it is well to start by naming three months as the earliest time for the duration of treatment.

The patient must be careful not to over-exercise or overwork till exhausted, as this allows the disease to take fresh hold, and no horse-riding, bicycling or long motor rides must be permitted, as constant bumping of the prostate is most harmful. No sexual excitement of any kind is to be permitted, as it at once sets back the favourable progress of treatment.

The patient will often complain of nocturnal pollutions. These can do nothing but good, as by this means the prostate is emptied of its contents with very little accompanying hyperæmia.

Not a drop of alcohol must pass the patient's lips till he is cured. Even a single glass of wine is often enough to cause a recrudescence of urethral discharge and to set back the clock of the disease for weeks.

The key to successful treatment is prostatic massage. If the disease is left to itself it takes years to die out and may persist indefinitely. The gland and its ducts become clogged with inflammatory products and no progress is possible. It is proved by experience that if the gland can only be emptied at regular intervals and without the hyperæmia attendant on sexual excitement the clogged ducts are cleared, the acini emptied of pus, fresh serum is poured out into the acini charged with bactericidal substances, the circulation of lymph is favoured whereby noxious products are carried away and the gland slowly but surely returns to the normal state.

After all the best antiseptic wash we know is healthy tissue fluid, and by this simple means we can secure that the whole gland is washed out with this fluid at regular intervals.

It is found by experience that massage should not be performed too often. Every fourth to seventh day is quite sufficient to secure a good result. It is also important not to persist too long with any given course. Four to six weeks should be the limit. At the end of that time all treatment should be put aside for at least three weeks and the patient should be persuaded to take a short holiday in sea air, either on board ship or playing golf at the seaside. Many a patient sent away like this with a fair amount of pus still present in his secretion returns without a trace of it and absolutely cured.

If this happy result is not attained a further course of massage should be instituted, and in nineteen cases out of twenty a perfect cure will in time be attained. In those cases which fail to clear up after some months it is as well to seek special advice.

The process of massage is very simple and only takes a few minutes. By means of a gloved finger inserted into the rectum of the kneeling patient the operator makes *gentle* pressure against the anterior wall of the rectum. The finger is made to work from without inwards and downwards towards the middle line over the back of the vesicles and prostate. In a minute or so a bead of secretion appears at the meatus and this is the signal that enough has been done. *No force must be used or the wall of the rectum may be torn.* Peaceful persuasion is here the motto. The patient then passes water and thereby washes out the urethra. An instillation should now be made into the deep urethra. This is done with an "Ultzmann" catheter and syringe which can be obtained from any instrument maker. The best solution is 5 gr. of silver nitrate in 1 oz. of distilled water, 1 dr. of which is used for each instillation.

There are no specific drugs for this complaint, but it is important to prescribe tonics, especially nux vomica and strychnine, which help to raise the tone of the prostatic musculature and brace the patient's nervous system and keep him from worrying.

New Growths of the Prostate.—These are simple fibro-adenoma (90 per cent.) and carcinoma (10 per cent.). They are seldom met with under the age of fifty. The early symptoms are increased frequency of and difficulty in micturition and hæmaturia. The second stage is marked by attacks of acute painful retention. In the last stage appears the giant toneless painless bladder that overflows every few minutes. The diagnosis is made by rectal examination and *by cystoscopy*.

The treatment may be symptomatic or curative by removal of the cause.

Symptomatic. General Treatment.—Most of these patients will be found to have a high blood pressure, and this should always be measured. If found excessive the general directions for those with high blood pressure must then be reviewed for the patient's benefit. "Moderation in all things" is the motto. No rushing to catch a train, no straining at stool, no straining to pass water, and moderation in the sexual life. There is great risk from a sudden exposure to chill, so that careful attention must be directed to questions of climate, dwelling-house, ventilation, bathing, bed-clothes and dress. The attacks of acute painful retention are brought on by anything that drives the blood away from the surface and produces congestion of the portal and pelvic veins. Such things are chill, constipation and heavy meals.

A moderate, light, mixed diet is therefore to be prescribed, and only the lighter forms of alcohol should be taken, and those in small amounts. So long as there is no unrelieved obstruction a glass of diuretic table water such as Evian, Vichy or Contrexeville should be drunk on an empty stomach, morning and evening, with the object of flushing the kidney tubules. As regards drugs, remarkable amelioration of the symptoms can usually be secured for some years by their use.

In this connection I have found the best mixture to be one containing 3 gr. of urotropin and 20 gr. of acid sodium phosphate. If this fails to relieve the symptoms nux vomica or ergot will often succeed, and nitric acid and phosphoric acid may also be worth a trial.

Symptomatic treatment includes the use of the catheter. The catheter should be used if there is an attack of complete painful retention, but only after the patient has been given a hot bath and has been put to bed in blankets, during which time the doctor can have made all his preparations to pass a catheter with aseptic ritual. The best catheter is a No. 10 English

scale black or yellow gum-elastic, called "the Marshall," supplied by Bell and Croyden. The best lubricants are "catheter purin" or the "K-Y lubricant" which can be obtained in tubes. Draw off 20 oz. of water every four hours until the bladder is empty, by which time the patient will usually be able to pass water again naturally.

If the frequency at night is so great as seriously to disturb the patient's sleep, it may be necessary to pass a catheter last thing at night, but such patients would be far better advised to undergo an operation. I never prescribe catheter life unless—

1. The kidneys are so far gone that an operation is inadvisable, the patient being unable to micturate at all, or the bladder filling up so quickly owing to polyuria that it needs relief every few hours.

2. The patient refuses operation and there is enough residual urine for the bladder to be palpable above the pubes, or there is chronic cystitis which requires lavage.

In the ordinary cases with only a small amount of residual urine I am of opinion that the patient, if he refuses operation, is far more comfortable and runs less risk if he has no catheter treatment. The profession have been far too ready in the past to have resort to the catheter. The mortality from the catheter is greater than that from operation. The catheter should never be used for *diagnosis* of the amount of residual urine.

3. As a preliminary course for patients with partial renal failure so as to relieve the kidneys of their load and put them in a fit state to withstand an operation.

Curative Treatment.—Modern medicine endeavours to replace symptomatic treatment by treatment based on knowledge of pathology and aims at removing the cause of a disease. Modern surgery may be said to have conquered most of the difficulties that surround the removal of the cause when Freyer can publish a series of 1,036 cases with 57 deaths, and Young can publish a series of 450 cases with 17 deaths. These results can, of course, only be obtained by those who practise the operation assiduously.

I have recently published (*American Journal of Dermatology* August 1912) a consecutive series of cases of my own operations performed half under stovaine spinal anæsthesia and half under general anæsthesia on patients as they came up to a large general hospital in all stages of the complaint, no case being refused operation, no preliminary treatment being employed. By this means I was able to prove that cases of adenoma of the prostate can be divided into three groups as regards operative mortality.

The first group includes those who complain of irritability of the bladder with or without attacks of painful retention of urine, but who show no signs of renal failure (functional tests)

In this group the mortality was nil.

The second group includes cases with similar symptoms, but who also show signs of renal failure. In this group the mortality was nil when stovaine spinal anæsthesia was used, but was higher when chloroform was used.

The third group is distinguished from the others by the fact that the patients complain of passing water every few minutes and on examination is found a painless atonic distended bladder extending to the umbilicus. In this group the mortality was very high whichever anæsthetic was used.

These facts show the extreme importance of knowing how to select the right cases for operation if the mortality is to be nil or almost nil. The mortality in the last two groups might seem at first sight too high to justify operation at all, but by recent work I have now satisfied myself that even in these groups the mortality can be reduced to a low figure *if three months preliminary treatment is employed of regular catheterisation*, copious drinking and administration of urotropin, or, better still, permanent drainage by suprapubic cystotomy.

There is, therefore, no need to refuse operation flatly to patients within these latter two groups, but it must be refused unless preliminary treatment has been carried out for three months or longer until the functional tests show that the kidneys have recovered their power. (The functional tests cannot be described in this article.)

These facts also indicate the necessity of urging operation during the first few years of the complaint, when the operation is not dangerous and a complete cure can be promised.

It is not fair to treat these patients symptomatically for years until their bladders and kidneys are worn out and then expect the surgeon to operate on them when the proper time for the operation is passed.

Summary.—Catheter life never cures, it only relieves symptoms, it is far more dangerous than most people realise and it is the source of much worry and loss of time. In its favour can be urged that it seems a far less dangerous step to the patient and his friends, and these considerations may be allowed due weight when the patient can afford the time and care required to carry out the catheter ritual.

Three months' course of catheter life or drainage by suprapubic cystotomy should always be prescribed before proceeding to operation in those whose kidneys show definite signs of diminished power. On the other hand, operation seems a big step to take and presents a certain amount of immediate risk and acute discomfort; but in its favour can be urged that the risk is

smaller the earlier the patient presents himself for operation, and that three months after the operation the patient will find himself cured of his obstruction for good and all. That is to say, he will never need the catheter again, the stream will be free, the urine will be clear, the frequency will be normal and the kidneys will be saved from slow death by back pressure and infection. The warmest advocates for the operation are those who have passed through it themselves.

At the same time it is well to remember that good results can only be obtained by those who practise the operation constantly. Only by this means is it possible to ensure that the diseased gland is delivered cleanly and quickly; that the patients are selected wisely; and most important of all that all those minute details in the after-treatment be attended to which do so much to put the finish on a successful operative removal. F. K.

INFLAMMATION OF THE BLADDER

A patient suffering from cystitis complains of pain in the bladder region and at the end of the penis, increased frequency of micturition and the passage of pus and blood. It is a common mistake to make a diagnosis of *cystitis* when, as a matter of fact, the patient is suffering either from *pyelitis* or *prostatitis*. In these two conditions cystitis, if present, is only a minor incident.

If fever is present the case cannot be one of pure cystitis. Fever with pyuria in a woman is always pyelitis, and in a man is usually prostatitis. This is a most useful diagnostic rule. The diagnosis of cystitis from pyelitis can be made in the following manner. The urine should be passed into two glasses. If the second is cloudy the case may be either cystitis or pyelitis. If there is fever it must be pyelitis.

If there is no fever the diagnosis can only be made by cystoscopy and catheterisation of the ureters. In some cases there may be a large tender kidney, which renders the diagnosis easy, but in other cases there may be no symptoms pointing to the kidney. In the male the diagnosis of cystitis has also to be made from posterior urethritis and prostatitis. The patient is asked to urinate into two glasses; if the second is clear the case cannot be one of cystitis, and the pus must be coming from the urethra. The contents of the prostrate gland are then expressed by means of gentle pressure of a gloved finger inserted into the rectum. A drop of the secretion is caught on a slide and should be examined under a microscope, and of another drop a culture is made. Microscopic examination shows the presence of pus cells and bacteria. The culture reveals the nature of the bacteria. It cannot be too often emphasised that most male patients with fever, rigors and pyuria are cases of prostatitis. Such a prostatitis may be secondary to gonorrhœa, but is very often a spontaneous infection with the colon bacillus.

Pyelitis and prostatitis having been excluded, a diagnosis of cystitis is not yet sufficient. In the first place it is necessary to determine the exciting cause, namely, the organism by means of film preparations, cultures and inoculation experiment in order to determine if it be the tubercle bacillus, the colon bacillus, the gonococcus, a streptococcus, a staphylococcus or a proteus. These are the only bacteria that commonly infect the urinary tract. (At this point it is well to state that if the tubercle bacillus is found the primary focus must be either in the testis or the kidney. Primary tuberculous cystitis is unknown.)

Having determined the bacteria present, the practitioner must not rest content, but must proceed to find out finally whether there are any predisposing causes present. It is not uncommon to meet with patients at the present day who have been treated for months with emulsions of bacteria isolated from purulent urine with no improvement ("vaccine" treatment). When these cases come to be examined in a proper manner the reason becomes clear, usually a stricture is present, or an enlarged prostate or a stone. Naturally such cases will not clear up until these predisposing causes have received proper surgical attention. The common predisposing causes of cystitis are as follows: Stricture and enlarged prostate, stone, tumour, diseases of the nervous system and the passage of unclean instruments. Uncommon causes are: foreign bodies, parasites, pouches. Until all these have been excluded it cannot be said that the case has been properly examined.

When the diagnosis has been rendered complete the practitioner can proceed to the consideration of the treatment. If a predisposing cause is present it should be removed whenever feasible, the cystitis will then usually clear up forthwith in a few weeks. On the other hand, no predisposing cause may be found. A certain number of cases of hæmatogenous spontaneous cases of cystitis are met with, especially in young males. The onset is usually acute, with considerable hæmorrhage, though it may be insidious and with slight hæmorrhage, the organism concerned being usually the proteus. If the bladder is inspected with the cystoscope ulceration is usually present, and the inflammation may be found to be confined to the bladder only. Such cases tend to clear up spontaneously in three to four weeks' time, though a few become chronic. There need, therefore, be no surprise if there is failure to find a predisposing cause.

Treatment of Acute Cystitis.—No lavage or instrumentation should be employed at the outset when the symptoms are acute. Resort must be had to general measure. Rest in bed, the application of heat by means of hot-water bottles, poultices, hot enemata and hot hip-baths will be found of great service, and the application of half a dozen leeches to the perineum brings relief. The patient should drink large quantities of fluid, as the more dilute the urine the less will it irritate the inflamed bladder. The diet should consist of milk only, and alcohol should be strictly forbidden. Sedatives will be needed, and are best applied in the form of suppositories, the most satisfactory being one that contains 1½ gr. of the extract of belladonna, 20 gr. of antipyrin, and 14 gr. of the oil of theobroma. If this fails to control the pain morphia or laudanum is required.

During the acute stage there should be no thought of trying to kill the bacteria by means of drugs. The indication is to render the urine as little irritating to the bladder as possible, and leave the killing of bacteria to the natural antiseptics contained in the inflammatory exudate. Acid urine is more irritating than alkaline urine, so that the wise course is to give alkalies. A good mixture contains 20 gr. of potassium citrate, 20 min. of the tincture of hyoscyamus, 10 min. of the emulsion of chloroform, and is made up to the ounce with the infusion of uva ursi. It may be given every four to six hours. In a few days the symptom should subside under this régime, and the case may clear up entirely by natural repair, or it may become chronic.

In the treatment of chronic cystitis it is of the utmost importance to attend to the general health. The patient must be warmly clad, and, if possible, should be removed to a warm seaside place on the south coast. He should be encouraged to live in the fresh air and to take plenty of good food, aided thereto by an appetising tonic. He should drink at least four pints of fluid in the twenty-four hours, and more if he can manage it—preferably Contrexéville, Evian, or Vichy water, and only the mildest forms of exercise should be permitted.

In the treatment of chronic cystitis two further principles are employed, namely, lavage and the administration of urinary antiseptics.

1. **Lavage.**—Lavage is especially indicated for cases with ammoniacal urine. The urine is rendered ammoniacal by the presence of certain bacteria, usually the proteus or a staphylococcus which can split the urea into ammonium carbonate and ammonia. It is very difficult to kill these bacteria by means of urinary antiseptics taken through the mouth. The indication is to diminish the bacteria by lavage, when it may be possible to restore the acid reaction of the urine and then obtain the full effects of urinary antiseptics. In ammoniacal cases, while lavage is being carried on, the following mixture should be given, for reasons which will be explained later: boric acid 15 gr., ammonium benzoate 15 gr., emulsion of chloroform 10 min., infusion of uva ursi to the ounce. Lavage should be carried out twice a day if the bladder is not too irritable. If the washings are found to irritate they should be carried out once a day, or even less often, until the bladder becomes more tolerant. The best method for washing the bladder is the method of Janet, by means of hydrostatic pressure. It is the best method because no catheter is required. The apparatus needed can be obtained from Montague, of 69 New Bond Street, and is known as the author's outfit. It consists of an india-rubber bag to hold two pints of fluid, which can be hung on a nail in the wall at a height of five feet above the patient's abdomen. To the bag are attached six feet of rubber tubing and a glass nozzle. The bag having been filled with lotion the fluid is made to run, by the force of gravity, into the urethra through the sphincter of the bladder into the bladder itself. The patient soon learns to take the fluid into the bladder, and after a few minutes he passes it out again naturally.

The other method of lavage is to pass a catheter and wash out the bladder either with a syringe or with the irrigating bag. This method must always be used in the female, but should only be used in the male if there is some additional reason for passing a catheter, such as an enlarged prostate.

When the bladder has been rendered tolerant with simple washings a complete and rapid cure can often be obtained by means of instillations into the bladder of 30 min. of strong silver nitrate solution, beginning at 5 gr. to the oz. and working up to 20 gr. to the oz. These instillations are introduced by means of "Ultzmann's instillator." A lubricant is needed, and the best is the "K.Y." lubricant. In obstinate cases which fail to react to these methods a cure can sometimes be obtained by means of suprapubic drainage for a few weeks, which acts by giving the bladder complete rest.

For lavage the following solutions may be employed: silver nitrate in strengths running from $\frac{1}{10,000}$ up to $\frac{1}{1000}$ in ordinary tap water. Oxycyanide of mercury in strengths of $\frac{1}{4000}$ up to $\frac{1}{2000}$. Zinc permanganate $\frac{1}{4000}$.

In obstinate cases I have obtained remarkable cures with "gomenol," a patent preparation made up by Prevet of Paris. Forty min. of gomenol are added to two pints of warm water and thoroughly shaken up in a bottle, the resulting emulsion being used as a wash. If the case is not doing well on one kind of solution it will often react if a trial be made of others,

though it is impossible to predict in any particular case which particular solution is going to give a favourable result.

Urinary Antiseptics.—A good deal of work, from the clinical standpoint, has been carried out recently on urinary antiseptics, especially by Anson Jordan and Thomson Walker.

1. In acute cases it is not wise to exhibit drugs that act only in an acid medium. In such cases potassium citrate is the drug which relieves the symptoms, though it does nothing to diminish the bacteria. It is best made up with the infusion of uva ursi, which exercises a sedative effect and has a distinct antiseptic action even in alkaline urines.

2. In chronic cases, if the urine is ammoniacal or alkaline, it is not the slightest use exhibiting urotropin and allied drugs. This class of compounds act by producing formaldehyde in the presence of acid urine, but they are quite unable to do so in an alkaline urine. The antiseptic action is entirely due to the formaldehyde. In alkaline urine, therefore, lavage is the most important method for eliminating bacteria. Drugs that are bactericidal in alkaline urine are boric acid and uva ursi. Boric acid appears to be the most valuable drug of all, and should be given in doses of 15 to 25 gr. four times a day. Ammonium benzoate renders the urine less alkaline and should be exhibited as an adjuvant.

If the alkalising bacterium is a staphylococcus it is an indication to use sandal-wood oil, as sandal-wood oil appears to be highly bactericidal to staphylococci, but even in cases of alkaline cystitis due to other bacteria sandal-wood oil often has a most soothing influence, and will be found to be of great value as regards the symptoms. It is best given as an emulsion made up with Tr. of Quillaia or mucilage, in doses of 5–15 min. four times a day. In certain persons it causes backache or stomach ache, and must then be discontinued. It has no real bactericidal effect on gonococci.

3. If by such means the urine can be turned faintly acid, and anyhow in chronic cases with acid urine, then is the time to exhibit urotropin. Urotropin seems to be the most powerful bactericidal agent that can be given by the mouth, but can act only in acid urines. The more highly acid the urine the higher the concentration of formaldehyde, and, therefore, the better the result. In addition to urotropin drugs should be given which increase the acidity of the urine. The best of these is acid sodium phosphate, in doses of 30 grains four times a day.

4. Certain practical points must be mentioned with regard to "urotropin." Urotropin decomposes very quickly in a mixture, and should, therefore, only be given in tabloid form. These tabloids are to be dissolved in water by the patient. Urotropin can be given in larger doses than has hitherto been given. In obstinate cases it is possible to administer 20 gr. four times a day, but in most cases a sufficient dose will be 3, 5, 7½ or 10 gr. Urotropin should be given at least six-hourly, as the major part of the drug is secreted during that time. Certain patients will not tolerate urotropin. Even the minutest trace of formaldehyde in the urine in such patients may cause a most intense irritation of the bladder. It is also stated that certain persons cannot change urotropin into formaldehyde, and this may be why it fails to act in some cases. Finally in a few persons urotropin will be found to irritate the stomach, and here again it must be discontinued. It is no use giving urotropin with alkalies, and that is why urotropin is superior to any of the patent combinations of hexa-methylene-tetramine in combination with citrates, etc. If urotropin is not tolerated it is better to make use of boric acid and the benzoates, or of sandal-wood oil. Salol has been lauded in doses of 20 gr., especially by Rovsing, but in other hands it has been found disappointing as a urinary antiseptic.

5. The following points will be found to bear on the subject under consideration. However acid or however alkaline the urine is made no effect is produced on the growth of colon bacilli. All the same, during acute B. coli infections, alkalies do relieve the symptoms, and during the chronic stages acids help by increasing the action of urotropin, which does inhibit the growth of colon bacilli. The best drug for rendering the urine alkaline is potassium citrate. The best drug for rendering the urine more acid, if it is already acid, is acid sodium phosphate; but when the urine has been rendered alkaline by bacteria the best drugs to turn it acid are boric acid and ammonium benzoate.

6. Finally a few words should be written on the treatment by vaccines. In a case of tuberculous cystitis, tuberculin will only cure if the cystitis is secondary to a tuberculous testis, and in such case the cure will usually be obtained rapidly. If, on the other hand, there is no tuberculous nodule in the testis, and, of course, in all cases in females, then there is always a primary tuberculous infection of one kidney, and a cure is absolutely impossible unless the affected kidney be removed. When that is done tuberculin rapidly clears the cystitis, but if that is not done the condition may seem to improve for a time, but will eventually relapse and lead to the death of the patient. In the case of infection with the colon bacillus autogenous vaccine will often relieve the symptoms, but they will not rid the urine of bacteria. To attain this end the predisposing causes must receive attention, urinary antiseptics must be

given, and the bladder must be treated by lavage, when a cure can usually be obtained.

Other diseases of the bladder are calculus, neoplasm and parasites. Apart from associated cystitis their treatment is carried out by cystoscopy and surgical manipulations, and cannot, therefore, be considered here.

During the course of certain diseases of the nervous system, and also in the course of certain febrile and asthenic states, retention of urine may occur, and need for its relief the passage of a catheter. The precautions in vogue to ensure surgical cleanliness in catheterisation are not nearly stringent enough if cystitis is to be avoided. It has, therefore, been thought well to insert in this place directions for the passage of a catheter which do satisfy the canons of aseptic surgery and are found in practice to prevent effectually infection of the bladder. Though the description may seem a little prolix the time actually consumed in carrying out the manipulations is not long when all the apparatus required has been assembled, and the practitioner is accustomed to their routine use. It is not right to pass catheters in a light-hearted manner, as if they were simple and safe instruments. They are safe instruments if properly used, but their use is never simple, and requires religious attention to the details of aseptic ritual.

The outfit needed must include the following articles, and can be obtained from Montague & Co., 69 New Bond Street: (1) A douche tin or india-rubber douche bag to hold two pints; (2) six feet of rubber tubing and a clip; (3) a tin jug in which to make up a wash; (4) material for making up an antiseptic wash; (5) a urethral nozzle of some kind; (6) a sterile lubricant; (7) a suitable catheter; (8) some arrangement for sterilising the catheter.

The best lubricant is made up as follows—glycerine 20 parts, tragacanth 2 parts, oxycyanide of mercury $\frac{1}{4}$ part, sterilised distilled water 100 parts. This is put up in ordinary tin squeeze tubes, and is easily carried about and always ready for use. It can be bought ready made as the "K.Y. lubricant."

A No. 9 or 10 (English scale) gum elastic coudé is a good form of catheter, but perhaps the best of all is the "Marshall," made by Bell and Croyden, with a hard olivary tip, a flexible shaft and a large eye. The latter can be boiled many times, and indeed most of the best instrument makers now turn out gum elastic catheters that can be boiled. Porgés white gum elastic is as good as any of them.

After a catheter has been mechanically cleaned, boiled and dried it is best put away in a "paraform" steriliser. A catheter can be carried about anywhere in this, where it lies constantly in dry formalin vapour. In emergency work the practitioner is advised always to boil his catheter just before use. Better to spoil many catheters than to spoil one patient. An outfit for catheterisation of prostatic cases (known as the author's Prostatic outfit) is kept ready for use by Montague.

The normal urethra swarms with bacteria in its first three inches, but higher up it is sterile. The urethra must, therefore, be washed out before a catheter is passed. The best antiseptic wash for this purpose is oxycyanide of mercury, one part in four thousand of warm water. This drug may be obtained in tabloid form. If it is not to hand a 15 gr. tabloid of chinosol dissolved in a quart of warm water makes an efficient and non-irritating wash, as does a solution of lysol, $\frac{1}{2}$ dr. to a quart.

The douche bag or tin is filled with two pints of wash and suspended by a nail or held by an assistant some two or three feet above the level of the patient's penis as he lies in bed. Clipping the rubber tubing with the first finger and thumb just above the urethral nozzle which is attached to the end of the tubing, the practitioner places the nozzle just inside the urethra and allows a gentle stream to flow into the urethra and back again around the nozzle into a receptacle placed beneath the penis. The urethra, as far as the compressor urethræ, is in this way flushed with a pint or more of the wash, and is rendered sterile for the time being.

Having washed his hands in an antiseptic lotion the practitioner takes the catheter and passes it into the bladder. If the bladder is over full not more than twenty ounces of urine should be withdrawn, as if the bladder is completely emptied the sudden relief of pressure may act adversely in two ways. First, the splanchnic veins may fill up with blood, and the heart, being deprived of sufficient blood, may fail. Secondly, the renal veins may become so engorged with blood from the relief of both intra-abdominal and intra-ureteric pressure that the kidneys may stop work, with consequent anuria. A single catheterisation is often sufficient to enable the patient to pass water again naturally. If not, the procedure must be repeated every six hours until the bladder is empty, twenty ounces being drawn off each time, and after that be passed at least three times a day. F. K.

TREATMENT OF DISEASES OF THE DUCTLESS GLANDS

DISEASES OF THE THYREOID GLAND

Thyreoid Medication.—For the treatment of disease by means of thyreoid extract there are two golden rules: one, to keep the dosage, especially the initial dosage, as low as possible; the other, to maintain a close supervision of the patient. The method so much in vogue of giving 3–10 gr. three times daily cannot be too strongly condemned. The initial dose should never exceed $\frac{1}{10}$ – 1 gr. three times a day, and even so a careful watch should be kept for symptoms of intolerance. It should never be forgotten that the more urgently in need of thyreoid extract a patient stands the smaller will be his tolerance of it. Tachycardia, high temperature, mental symptoms, emaciation, vomiting and diarrhœa are all indicative of a high degree of intolerance, and their appearance carries with it a suggestion of grave mismanagement. The recumbent pulse-rate should never be allowed to go above ninety-five, and when the temperature rises to normal the drug should be suspended for a time. It is a safe plan, especially when giving thyreoid extract over long periods of time, to intermit the treatment for one week in every four. In the case of women, it is as well to arrange that this interval shall coincide with the menstrual period. The first subjective sign of thyreoid intolerance is a consciousness of the heart's action, unaccompanied, however, by anything approaching tachycardia. Another frequent sign is a coryza very similar to that provoked by iodide of potassium. In the case of children a reliable guide is provided by the weight chart: as long as weight rises the drug is well borne; when it becomes stationary the drug should be suspended; while a falling figure is invariably a sign of intolerance and calls for discontinuance of the treatment.

The effect of thyreoid extract is considerably enhanced if it is exhibited in combination with three other drugs, namely, iodine, arsenic and calcium. These may be given in a mixture—

℞ Calcii iodid. gr. v
Liq. Arsenicalis ♏ ii
Aq. Chlorof. ad. ℥ ss ter post cib.

which should be suspended every fourth week coincidently with the thyreoid extract.

It is always advisable to modify the diet of a patient under treatment with thyreoid. The amount of meat foods and of alcohol should be very much reduced and salt should be excluded from the dietary. In all forms of thyreoid inadequacy muscular asthenia is present, sometimes in a very high degree. For this reason massage is as beneficial and as grateful as general exercise is harmful and unwelcome.

Success with thyreoid therapy is dependent, and to an extent which is not always realised, upon the employment of a reliable preparation. The tabloids of Messrs. Burroughs and Wellcome are made in minimal doses of $\frac{1}{4}$ gr. (equal to 10 gr. of the dried extract) and they are entirely trustworthy. Elixir Colloid (Squire) is a liquid preparation of great reliability. Its form permits of minute dosage, while its name effectually conceals its identity from the laity —a point of no small importance when dealing with cases of a certain class.

Thyreoid Inadequacy.—Minor degrees of thyreoid insufficiency are of far commoner occurrence than is generally assumed to be the case. Babies who do not thrive are frequently the victims of such a condition; they can sometimes be made to improve by the judicious exhibition of a combination of thyreoid extract and grey powder. Rickets, adenoids, nocturnal enuresis, enlarged glands, a tendency to "catch" anything which is going about, all suggest a state of subthyreoidism in children. Such a state may be congenital, or it may be the outcome of the starvation of the gland by one of the febrile diseases incidental to childhood. True influenza is a severe thyreoid depressant and recovery is both easier and more rapid where thyreoid extract is exhibited during convalescence. States of minor thyreoid inadequacy are frequently seen in women at puberty, at menstruation, during pregnancy and lactation, and at the menopause. Thyreoid medication is invariably beneficial in these conditions. Pregnancy makes a very prolonged demand upon the resources of the thyreoid gland and, in consequence of the subsequent reaction, the mother is frequently unable to suckle the infant. Here again a careful thyreoid medication sometimes works wonders, not only in promoting the secretion of milk, but in materially relieving the difficulties incidental to the post-partum state. Certain forms of obesity (see article on *Obesity*), which make their appearance towards middle life in men as well as in women, yield to thyreoid extract given in small doses in combination with other measures. Many of the stigmata of old age point indisputably to an exhausted thyreoid gland; such are the chilliness, dry skin, baldness, slow pulse-rate. In cases where there is no reason to suspect the condition of the heart and the arteries, judicious, *very* judicious, thyreoid medication will sometimes produce a sense of well-being in these old people to which they have long been unaccustomed.

Nocturnal Enuresis.—Nocturnal incontinence of urine in children may be the outcome of a variety of predisposing causes of which by far the commonest is thyreoid inadequacy. In the vast majority of cases it will be found that children who habitually, or even frequently, wet their bed are undersized; that they have a high arched palate and imperfect teeth; and that they suffer from a subnormal temperature which is lowest at night. All these signs inevitably point to a lack of the internal secretion of the thyreoid. The condition is best treated by thyreoid extract or by the salts of calcium, whose property it is to stimulate thyreoid activity. In certain cases both methods may be combined with advantage. Thyreoid medication should be initiated with extreme caution. A half grain tabloid (Burroughs and Wellcome) once a day is a safe dose for a child of five, and, if well borne, may be gradually increased until the child is taking ½ gr. three times daily. A careful watch should be kept upon the pulse and temperature and upon the weight. A rise in all three is an indication that the dose is sufficient; a fall in weight shows that it is excessive. As long as the temperature remains subnormal thyreoid may be exhibited; as soon as the night temperature reaches the normal caution is necessary. The pulse-rate should never be allowed to exceed that proper to the age of the child, and the onset of a sudden and violent nasal catarrh should be taken as a warning to suspend treatment. Upon all counts it is wiser to suspend the treatment for one week in every four, and this applies equally to calcium, arsenic and iodine, whether exhibited alone or concurrently with the thyreoid extract. For reasons already given a mixture such as the following is a valuable reinforcement to thyreoid treatment, and in minor cases may alone suffice to control the enuresis. The dosage is estimated for a child of eight years.

℞ Calcii Iodid. gr. ii
Liq. Arsenicalis ♏ ii

Syrup Aurantii ʒ i
Aquam ad. ℥ ss.
M. sig. ter die post cib.

Patience and perseverance are factors of cardinal importance in the management of nocturnal enuresis. Unless these little patients are encouraged to form regular habits the most perfectly calculated system of medication is liable to prove disappointing in its results. Incontinent children should not only empty the bladder before going to bed; they should be aroused once in the night between ten and twelve, and they should be made to micturate immediately upon waking in the morning. This warning is the more necessary as children who wet their bed are frequently lethargic and unenterprising. Moreover, nocturnal incontinence is apt to be regarded by both mother and nurse either as a visitation from the hand of God against which it is useless to strive, or as a transient phenomenon which the child will "grow out of."

In spite of the general success of a thyreoid therapy in nocturnal enuresis, there is a small proportion of cases which, though characterised by all the appearances of thyreoid inadequacy, do not respond to treatment. It is probable that some gland other than the thyreoid is here at fault. Suprarenal extract in doses of 20 to 30 drops a day has been employed with success for children of four to fourteen years of age. Pituitary has so far proved useless, though the results obtained with thymus seem to be encouraging. Belladonna or atropine should be employed only when all other means have failed.

Myxœdema and Cretinism.—Both myxœdema and cretinism are the expression of pronounced thyreoid insufficiency. Treatment consists in the nicely calculated exhibition of thyreoid extract. In the case of the cretin, the earlier it comes under treatment the better will be the results obtained. Under careful management the bodily development proceeds at a pace and to a degree which is very striking, while the improvement upon the mental side is little short of marvellous. Conditions closely resembling cretinism and myxœdema are occasionally provoked by some error in function on the part of the hypophysis. For this reason, in cases which prove intractable to thyreoid the treatment should be supplemented by the exhibition of hypophyseal extract. Where the treatment by thyreoid extract not only fails to ameliorate the condition but produces symptoms of intolerance, it should be discontinued and hypophyseal extract employed in its stead. The best method is the intramuscular injection of 1½ gr. of the fluid extract three times a day. It should be remembered that this has a marked effect in raising blood pressure, which, unless the patient is carefully watched, may rise to a figure which is dangerously high.

Infantilism.—Several types of infantilism are recognised, and all are referable to absence or insufficiency of function on the part of one or more of the internal secretory glands. The actual causative factors are not, however, as yet identified. Hence treatment resolves itself into a more or less tentative endeavour to re-establish the deranged balance by supplying or supplementing the supposed failing secretion. Thyreoid extract should always be given first, and if this fail recourse should be had to pancreatic extract, which has been warmly

recommended in this connection. Hypophyseal extract should also be tried, that is the extract of the anterior lobe, or an extract of the whole gland.

It is well to remember the beneficial influence of fresh air, good plain food, and light warm clothing in all conditions which in any way approach infantilism. Red meat and alcohol should be excluded from the diet, and physical exercise should always be well short of fatigue. On the other hand, massage two or three times a week is a valuable adjunct to treatment, and a warm bath at night (100° F.) induces sleep and promotes metabolism.

Inflammation and Enlargement of the Thyreoid Gland.—Under certain physiological conditions, such as puberty, menstruation and pregnancy, the thyreoid gland sometimes enlarges and becomes tender, as if in response to an increased demand. Such hypertrophy is frequently only transient and passes off as the condition to which it owes its origin subsides. On the other hand, the symptom may persist and may prove to be the commencement of a goitre. In the case of pregnant women the sign is significant. It constitutes a warning that the supply of thyreoid secretion is insufficient for both mother and child, and serious harm may result if this warning goes unheeded. Thyreoid extract should be exhibited in small doses and, unless the symptom disappears, the treatment should be continued during the entire term of pregnancy.

That the thyreoid becomes enlarged in all febrile conditions is well known. This is especially the case in typhoid fever, and the condition has been observed in malaria and in cholera. Congestion and inflammation of the thyreoid gland are by no means infrequent accompaniments of true rheumatism. Here the enlargement may become so severe as to give rise to pain in swallowing, dyspnœa and pressure effects of varying degrees of intensity, while the inflammatory process may even involve the trachea and the glottis. Mild degrees of inflammation are effectually treated by means of hot fomentations. Where the inflammation is severe and threatens to spread to the neighbouring structures, thus giving rise to dyspnœa and dysphagia, blood should be withdrawn by the local application of leeches. Three or even four should be used and these are best applied along the lower border of the inflamed area in such a way that the scars will later be concealed by the clothing. If these measures fail there is no alternative but to invoke the aid of the surgeon. Prompt surgical intervention is always indicated in one rather rare condition. I refer to those cases sometimes seen after typhoid fever, where the inflammatory process leads to suppuration.

Goitre.—If we exclude exophthalmic goitre and malignant disease, goitres may be of two types : (1) parenchymatous, and (2) adenomatous. Combinations of both forms are frequently encountered.

Goitre is endemic in certain districts. It is believed that infection is due to an amœba and that it is conveyed in the drinking water. Where the disease is slight and the patient young, he should at once be removed from the infected area. Failing this, it is indispensable that the water for his consumption shall be obtained from another and uncontaminated supply. The most valuable drugs are iodine and its preparations and thyreoid extract. Either method should be employed with extreme caution and the initial dosage should be kept low. Five min. tincture of iodine and 5 gr. potassium iodide given three times a day is sufficient to start with, and this dose may be gradually increased to three or four times the amount, provided always that the patient does not show signs of intolerance. In the case of thyreoid, 1–2 gr. in the course of the day is an ample initial dose, and this may be increased to 5 gr. a day if the pulse-rate does not become unduly high. In some cases better results are obtained if the iodide and the thyreoid are exhibited simultaneously. The local application of Ung. Potass. Iodid. may assist in reducing the size of the tumour, and a compress of adrenalin to the gland at night is a good adjuvant to treatment by the mouth. Mention should be made of McCarrison's vaccine treatment, which is said to produce very striking results.

Exophthalmic Goitre (*Graves's Disease*).—Under suitable treatment, the prognosis of Graves's disease may be said to be good as to life, but bad as to recovery. In a few isolated instances spontaneous recovery has been recorded, but such cases are rare. The tachycardia, which is so characteristic a feature of the disease, frequently leaves behind it an enlarged left ventricle and a blood pressure which remains persistently above the normal. Moreover, the mental associates of Graves's disease are of bad or very doubtful prognosis and, even where the physical symptoms have yielded to treatment, it is uncertain whether the patient is ever again to be trusted upon the mental side.

Treatment consists first and foremost in rest, both mental and physical. This point cannot be too strongly urged, especially as, in view of the restlessness and unreasonableness of patients suffering from Graves's disease, the conditions are difficult to obtain. The patient should be kept in bed for weeks or even months; even in very slight cases recovery will be far quicker if the patient will be persuaded to go to bed for a time. Once there she should be kept

there by hook or by crook, until the pulse-rate is normal or nearly so. A large, light room should be chosen with windows open day and night. Anything in the nature of physical exertion must be avoided, and the patient must be carefully shielded from worry and from mental excitement of all kinds. In view of the emaciation, sometimes considerable, by which Graves's disease is accompanied, the diet, though plain, should be generous. Little meat should be given, and alcohol should be rigorously excluded.

Typical Graves's disease is a condition of thyreoid excess and almost certainly of thyreoid perversion; as a general rule, therefore, thyreoid extract should not be exhibited. Pituitary and parathyreoid extracts have both been known to do good. The same may be said of bile salts, given by hypodermic injection. A valuable adjuvant to this treatment is a compress of a solution of adrenalin applied to the gland. The application of X-rays to the gland is warmly recommended by certain physicians of repute. The method is said not only to reduce the local enlargement, but materially to ameliorate the general symptoms of the disease. Inasmuch as the internal secretion of the thyreoid and that of the pancreas are in many respects antagonistic to one another, pancreatic extract in large doses ought theoretically to be helpful in Graves's disease. The results of such treatment have not, however, so far seemed encouraging. Belladonna and aspirin are sometimes useful in tiding over emergencies, but their continued employment is not to be encouraged.

Surgical intervention in Graves's disease is very rarely desirable. Mild cases will usually respond to medical treatment, and severe cases are not suitable for operation, as they most frequently succumb. It is the general experience that the mortality after operation for Graves's disease is extremely high. L. W.

DISEASES OF THE SUPRARENAL GLANDS

Addison's Disease.—This disease occurs only as the result of slow destruction of the suprarenal glands, that is of all parts of the gland, both cortex and medulla.

Animals survive experimental removal of the glands for one or two weeks. A few days after the operation weakness and loss of appetite appear, and together with that the phenomena of a lowered circulation with feeble, rapid heartbeat. The picture is clear and simple: there is nothing to suggest poisoning or aught else than depression of the circulation and loss of its driving power. Under such conditions any external strain may overpower the weak heart and suddenly determine death. On the other side may be quoted the extraordinary power of adrenalin, the active principle of the suprarenal medulla, to raise the blood pressure when injected within the veins. The deduction seems clear, that the muscular tone of the heart and blood-vessels depends on the suprarenals. Vasomotor nerves control the tone, this way and that: they do not alone maintain it, for animals readily survive removal of the visceral and vascular nerves. It is not the damage of the neighbouring nerves but the loss of the suprarenal glands in Addison's disease that leads to circulatory failure and death.

The consequent weakness of the heart governs every detail of the treatment of the patient. Unfortunately no drugs have been found to be of enduring value to raise the cardio-vascular tone. Digitalis and pituitary extract are alike of little avail, for the muscular tissues in the absence of the suprarenals react to therapeutic agents in an entirely abnormal way.

General Lines.—Physical rest must be as complete as possible, the heart being treated as carefully as it would be in the cardiac irregularities that may follow diphtheria. Lengthy examination of the patient should always be avoided. It has been proved that emotional anxiety or anæsthetisation rapidly exhaust the suprarenals of animals. Hence it is obvious that the small store of adrenalin in these patients must be husbanded by protecting them from all mental distress. Anæsthetics and surgical shock are highly dangerous.

Warmth is all important, and indeed is craved for by the sufferers. Provided that it does not cause a sense of chilliness, open air treatment may be employed.

Food must be frequent, light and nourishing. Alcohol in moderate quantities may give a satisfactory sense of *bien être*. Cod-liver oil and malt extract should be tried with caution, since they often excite nausea.

For the damaged gland itself nothing can be done. Addison's disease does not develop until both the glands are infected, so that it is impossible to contemplate surgical excision of either. Tuberculin is said to be harmful, perhaps by causing such a local reaction in the glands as to choke the scanty output of adrenalin by which life was just maintained.

Syphilitic disease of the glands has never been diagnosed and specifically treated. In cases of simple fibrotic atrophy the process may chance to stop, and the patient be spared for an invalid life.

But treatment cannot at present discriminate between these conditions. All that can be done is to husband the patient's strength by general and symptomatic measures, and hope that the pathological processes may abate—as does indeed occur in a few rare instances—before the glands are utterly destroyed, for death in that case must be the issue.

Organo-therapy, unfortunately, has not yet been found to be efficacious. On the rapidly advancing cases it certainly does not exert any definite benefit, just as no treatment succeeds in keeping glandless animals alive. Transplantation of gland tissue into the kidney or elsewhere may in time be found practicable and useful; but at present such surgery has shown nothing to justify the risk of the operation.

Nevertheless suprarenal extract is always worth a trial. The customary dosage is probably too small. If it is permissible to regard the aim as simply that of making good a deficiency of adrenalin, then it is necessary to know what is the daily output of adrenalin from normal glands. The glands of a healthy man contain together at least 10 mg. of adrenalin: the excretion of it into the blood stream is rapid and frequent, so that the amount consumed daily is probably large. A case of double thrombosis of the suprarenal veins, which the writer once observed, survived about two days. One might, then, conjecture that at least 3 mg., that is, 3 c.c. of a 1000 solution, should be supplied daily.

There may be advantage in using an extract of the entire gland. The dried gland is apt to lose its potency, and it is better to use fresh extract. A fresh sheep's gland—kept on ice until required—is ground up with saline solution and glycerine, filtered through muslin after standing half an hour, and the filtrate, which is fairly palatable with the sweet glycerine, at once taken. A rough rule is that 1 gm. of the entire gland contains 2 mg. of adrenalin, so that one or two glands may be taken daily. The commercial forms of adrenalin, whether extracted from the glands or the synthetic lævo-suprarenin, may also be given in 1 mg. (15–20 min. of 1 in 1000) doses t.d.s. well diluted with water after food. If it causes vomiting the treatment should at once be stopped.

For subcutaneous or intravenous injection only the pure principle should be employed. Adrenalin borate, in 0·5 or 1 mg. doses, rather than the chloride should be chosen for hypodermic administration, because the latter salt causes pain at the site of injection. The result is a rise of temperature and of blood pressure for the first day or two but, in the writer's experience, no lasting benefit. Intravenous injections, 1 mg. in 500 c.c. of normal saline, might be of value in critical periods, when the oft-quoted danger of inducing atheroma is negligible. It must not be forgotten that adrenalin is a poison, causing fatty changes in the kidney and liver, or death by coma when given in large quantities.

Symptomatic.—The general weakness and sense of coldness are met by general measures. Loss of appetite requires nux vomica, or occasionally arsenic. Pain in the epigastrium is rarely more than an uneasiness, but every endeavour must be made to save the patient even this discomfort. Constipation is to be controlled by petroleum emulsion, mild salines, or purgative pills. Strong cathartics or enemata may induce fatal collapse. Diarrhœa demands bismuth, opium and hot applications to the abdomen and buttocks.

Vomiting is among the worst of symptoms and the most difficult to treat. Bismuth, dilute hydrocyanic acid, drop doses of tincture of iodine, or champagne may be successful. Gastric lavage is to be deprecated, if it distresses the patient. Arguing that the vomiting might be due to over-action of the vagus in the failure of the sympathetic inhibitor nerves of the intestine, the writer in one case tried full doses of atropine, but without avail.

Acute syncopal attacks require hot applications over the precordium, strong coffee and brandy internally, and especially the intravenous injection of adrenalin. In animals the restorative effects of adrenalin on the heart are astonishing, though not enduring.

Suppression of urine occurs whenever the blood pressure falls to 60 mm. or so; but it calls for no special notice or treatment.

Other Diseases.—Brief mention may be made of some other pathological conditions that affect the suprarenal glands, though none of them call for special treatment. There is no evidence at present to justify the acceptance of a special group of clinical features as indicative of exaggerated suprarenal secretion, and there is certainly no hypertrophy of its medulla in cases of high blood pressure.

Hæmorrhages destroying the glands are not rare, for example in meningitis, infectious fevers, etc. They do not appear as a rule in purpuric conditions, and they are much more frequent in the fragile tissues of childhood. Surgical manipulations in the region of the kidney are at times done with a heavy hand, and the writer has seen a suprarenal completely destroyed by the resulting hæmorrhage in its lacerated substance. A man can, however, live perfectly well with a single suprarenal.

Simple adenomata of the cortical cells are often seen as yellow, fatty nodules embedded in the medulla. They develop at middle age, and occur especially in cases of interstitial nephritis or of tuberculosis. In the latter disease at autopsy they are sometimes mistaken for areas of tuberculous infection. They are innocent, insomuch as they do not cause pressure atrophy of the true secreting gland cells.

Malignant growths originating in the supra-

renal in adult life are not recognised until their characteristically hæmorrhagic secondary deposits occur in lung or in bone, and they have no special clinical picture apart from these deposits. But those occurring in young children being either sarcomatous or truly derived from the cortical gland cells, are in the latter case liable to be associated with remarkable precocity of sexual growth. Excision of the primary mass has always failed to save life on account of the early dissemination of secondary nodules.

T. R. E.

DISEASES OF THE HYPOPHYSIS CEREBRI

1. ACROMEGALY

In considering the treatment of acromegaly it is well to remember that the progress of the disease varies in its course and effects in different cases. It may be more or less rapid, or it may extend to thirty or forty years or more. Much will depend upon the occupation, position in life and habits of the patient. Its symptoms are many and varied; some being due to the effect of the alteration in size and function of the hypophysis cerebri, many are consequent upon the derangement of organs and regions arising from the thickening growth and pressure of their bony surroundings.

Many of the subjective phenomena, as well as nutritive and structural changes in soft tissues, arise indirectly from those causes. It may be that some of the circulatory changes are due to the influence of reflex effects of pressure upon nerves in their course. Integrity of the hypophysis cerebri seems essential for the control of the trophic nerves.

The headache, neuralgia and giddiness associated with the disease may be due to defects of vision that progressively arise and the congested and inflamed state of the membrane lining the ethmoidal and frontal sinuses and the nose, all due to, or aggravated by, the expansion, growth and distortion of the bones in the neighbourhood of the hypophysis cerebri consequent upon its growth and functional alteration. Much relief is afforded by careful correction of the vision from time to time by glasses. The ophthalmic surgeon is often the first to diagnose a case of acromegaly, as his help is sought early for the astigmatism so frequently present. This has to be corrected with suitable cylinders, but changes are periodically required owing to the alterations which may come on in the axis while the eye-ball is being squeezed or pressed upon by the thickened conchal bones,

Suitable applications by spray or douche to the nasal cavities and their neighbourhood will remove their secretion and discharges, and tend to reduce the hyperæmia and inflammation of them, which is associated with the hypertrophied bones and sinuses.

The douching of the nasal cavities is especially beneficial before going to bed, as it often enables the patient to have a good night which he might not otherwise have.

The treatment of the hypertrophied erectile tissue with the galvano-cautery will lead to its contraction and increase of the nasal airway. Sometimes when the airway is much obstructed by the more or less hypertrophied conchal bones, some bone may be advantageously removed.

Demulcent lozenges relieve the dryness of the tongue, which may amount to soreness, consequent on the mouth-breathing which is unavoidable when the nasal airway is much obstructed. Liquorice combined with menthol and eucalyptus is most useful and comforting. Menthol lozenges are so soothing in their effect also upon the headache and faceache that they appear to have a direct action upon the hypophysis cerebri. They may be used as a substitute for tobacco, for which the acromegalic generally has an intolerance.

The many drugs that have been used with varying success for the headache, neuralgia and "queer feelings" complained of in the course of the disease, include aspirin, phenacetin, phenalgin, quinine and morphia. The danger of giving morphia in such a chronic disease is obvious. It is to be avoided. Aspirin seems to be the most reliable notwithstanding that in some people it may increase the lethargy and depression which must be considered.

The greatest relief is derived from absolute rest—immobility—or allowing the tendency to sleep, which is a characteristic of the disease, to assert itself.

Several acromegalics have told the writer that "drugs may help, but I know I can get relief if I sit still for twenty or thirty minutes with my eyes closed."

The headaches are lessened in frequency and extent by care in diet, great moderation in exercise and the avoidance of much movement or shaking of the head, or conditions, such as vibration, from any cause, that may give rise to similar effects.

For the trophic changes in the feet a most useful treatment is the daily use of an electric footbath during the cold weather, as has been recommended by Dr. Lewis Jones, the bath consisting of a tub of warm water with an electrode of copper-plate at each end, and the battery of a simple me al induction-coil of smooth action, regulated to be as strong as can be borne with comfort. If used for a week or two now and then, it will improve the circulation in the feet and prevent, or even cure, the trophic ulcers liable to occur during the winter,

when the lower extremities so frequently suffer from local asphyxia or syncope.

The skin of the toes should be hardened by frequently painting them with friars' balsam.

The faradic footbath, besides having a local effect, is decidedly a tonic. More than anything else it improves the circulation and braces up the mucous membranes. It will influence the nasal catarrh and even cut short the severe colds in the head to which the acromegalic is so liable, besides having its effect on the lethargy and the fearful feeling of fatigue and weakness so characteristic of the disease.

The alterations in the mouth, produced by the growth of the lower jaw, and the want of apposition between the upper and lower teeth, will require the dentist's attention, which may also be of use in causing an early diagnosis of the disease. This is all the more necessary as the teeth are liable to be ruthlessly extracted owing to their malposition. Suitable metal dentures should be worn, capping the upper molars and filling up the gap between them and the lower ones. A fresh " bite " will thus be provided and the patient's digestion will benefit. The denture must be modified periodically as the jaw grows and advances. The patient's teeth will thus be saved, an advantage later on, as under the influence of the disease they are known to become extra hard and strong.

For the hypertrophied heart with the irregular pulse the line of treatment indicated is that of ordinary heart disease. An occasional course of digitalis or strophanthus (2 or 3 min. of the tincture) three times a day for a week or two, will steady the heart, improve the pulse and add to the patient's comfort. Small doses should be given, and for a short time only. This is important as the acromegalics are not very tolerant of drugs or alkaloids of any kind, including tea, coffee and tobacco.

The use of the faradic footbath already mentioned has a decidedly beneficial effect on the heart. The enlarged heart and the weakened muscles call for great moderation in exercise, and avoidance of fatigue.

Many are the drugs which have been used and good results have been obtained from putting the patient through a course of arsenic, quinine, iodide of potassium and even mercury. Of late, attention has principally been given to the glandular extracts, including the thyreoid, the testicular and the hypophyseal extract, but it is difficult to judge how far any improvement is actually due to the drug, owing to the uneven course which the disease runs, with great diminution and, at times, subsidence of some of the subjective symptoms. Dr. G. H. Gibson, of Edinburgh, has found the hypophyseal substance beneficial in some early cases and in later stages has found it relieve a number of subjective symptoms.

Thyreoid extract given in 5 gr. doses twice a day for several weeks has made the patient feel more comfortable and had a decidedly tonic effect. It is more reliable than hypophyseal extract, which, however, may raise the patient's blood pressure. The two extracts have been given in combination with apparently good results. Hypophyseal extract is certainly contra-indicated in certain stages of the disease when there is a state of hyperpituitarism and in some cases has been distinctly harmful. It has generally been given in tabloids of 2 gr. two or three times a day.

Operative Treatment.—To the difficulty of reaching the hypophysis cerebri, so deeply situated, and removing the portions of it which are diseased, or any new growth in the fossa hypophyseos, has to be added the danger of the wound becoming infected when it is made through unhealthy tissues, since the air passages are invariably unhealthy in acromegaly. The question is also increased by the difficulty of saying at what period of the disease it is justifiable, and the needlessness of operating in a case which runs a benign course, and in which later on most of the troublesome symptoms may subside. It seems only justifiable in a case which develops rapidly with acute symptoms, and in which the intense headache, the amaurosis, the vomiting, all point to a quickly growing tumour, possibly a sarcoma, at the base of the brain. The removal of it may save the patient's life. In some cases relief of the headaches has followed a trephining operation. Dr. Harvey Cushing has found that a subtemporal decompression is indicated to meet the general pressure disturbances. He has lately suggested in cases of profound secretory insufficiency the transplantation of a gland from another source. L. M.

2. OTHER DISEASES OF THE HYPOPHYSIS CEREBRI

The thyreoid gland presents problems for treatment in connection with: (1) excessive secretion and overgrowth, that is, exophthalmic goitre; (2) adenomata and colloid cysts of relatively inactive gland tissue, which are liable to hæmorrhagic distension and so produce symptoms connected with mechanical pressure on adjacent structures; (3) atrophy and secretory failure, with consequent myxœdema.

Very similar are the diseases of the hypophysis cerebri. Parallel to exophthalmic goitre is *acromegaly*, and just as the former disease may years later be succeeded by symptoms of myxœdema, so too is acromegaly liable to drift ultimately into a condition of hypopituitarism.

Adenomatous growths cause only pressure symptoms. Arising from the substance of the pituitary, they grow within the narrow confines of the fossa hypophyseos beneath the tightly stretched diaphragm of the dura mater. Symptoms of bitemporal headache arise from the tension of the dura; of loss of part of the visual field, especially a temporal hemianopia, from the pressure of the growth on the optic chiasma; and of actual hypopituitarism because the non-secreting adenoma compresses the true secreting cells. When the diagnosis has been established, the treatment is surgical. Headaches may be controlled by phenacetin and such drugs; but pressure on the optic nerve requires early relief. As the loss of vision is caused by direct pressure on the nerves and is not associated with optic neuritis, recovery after a successful operation may be good.

The method of approach elaborated by the American surgeons, Halstead and Cushing, causes no disfigurement of the face. The upper lip is everted, and an incision an inch long made into the mucous membrane across the labial frenum. From this a submucous tunnel is driven up the septum nasi, by removal of the vomer, and through the sphenoid bone to the base of the fossa hypophyseos. The dura covering the gland can then be opened by a cruciform incision. This mere release from pressure, a sellar decompression, suffices to allay the bitemporal headache, and may even restore vision, since it enables the growth to take a path of less resistance downwards into the naso-pharynx. The pressure may, however, be so great as to necessitate removal of part of the mass.

Larger tumours may burst through the diaphragma sellæ and, growing rapidly, give the general phenomena of cerebral tumour as well as blindness: these cases, with optic neuritis and signs of frontal or temporal lobe involvement, require a large cranial decompression. After decompression by either route, X-rays should be used to check the progress of the tumour.

Hypopituitarism is suggested when, in addition to showing the localising features of a glandular tumour, the patient becomes obese, lethargic and asexual. For this glandular therapy is required, either with or without a surgical decompression. Transplantation has not been proved to be of value. The gland extract may be taken by the mouth or injected subcutaneously. By the mouth, tablets containing 3 gr. of the entire dried gland of an ox or the equivalent of 6 gr. of the fresh moist gland may be taken t.d.s. The dose is raised until the patient exhibits slight glycosuria when given a test meal of 150 gm. glucose. No harmful results have been reported even with such huge quantities as 100 gr. t.d.s. of the dried glands.

Thyreoid extract may be used in addition. (See also *Diabetes Insipidus*.) There is no justification for trying adrenalin. T. R. E.

INFANTILISM AND SENILISM

For the purposes of treatment **Infantilism** may be divided into two great classes, in the one of which the cause is known and in the other is unknown.

Among the causes of infantilism the toxins undoubtedly hold a very important place, and in the word toxins we not only include the poisons of the infectious fevers, of tuberculosis, of syphilis, of malaria, but also the extrinsically formed toxins such as lead and alcohol. Evidently, therefore, each of these must as far as possible be eliminated before we can successfully treat any particular case of infantilism. Toxins exert a stunting effect upon development in one of two ways. They may act as starvation acts by giving rise to general debility, or they may exert a local effect upon some organ which ordinarily stimulates or controls development. The debilitating effect of the toxins may to some extent be counteracted by the more liberal administration of food during the course of a fever. Thus from this point of view it is important that no starvation tactics should be adopted in the treatment of acute rheumatism, of enteric fever, or indeed of any other microbial disease during infancy and childhood. It need hardly be added that the ordinary sanitary measures of a sufficient food supply, of fresh air, of cleanliness and of congenial surroundings are of capital importance in the treatment of all cases of infantilism.

Increasing attention is being directed to the significance of certain organs as centres for the regulation of growth and development. Chief among these are the thyreoid, pituitary, hypophysis cerebri, suprarenal, thymus and sex glands. In the symptoms which gather about any particular case of infantilism it is usual to find some which are predominant and are at the same time indicative of disturbance of one of these glands above all others. It is to these dominating symptoms that our efforts at treatment should be directed. Thus, if with a sluggish intelligence there is general lethargy with fatness, sensitiveness to cold, and a physiognomy suggestive of cretinism or myxœdema, extract of the thyreoid gland should be given, beginning, it may be, with one grain doses once a day and gradually increasing as in any ordinary case of cretinism or myxœdema. If fatness be the most conspicuous symptom it may be suspected that the hypophysis is inactive and that the infantilism is the expression of an

adiposo-genital dystrophy. In such cases Cushing advises that the whole hypophyseal gland should be given, beginning apparently with as many as fifteen fresh ox glands a day, or with their equivalent in the dried extract. It has been estimated that this remedy if given subcutaneously is four times more effective than if given by the mouth. In another case pigmentation of the skin, asthenia and a low blood pressure may point to the suprarenal glands as the chief defaulters, in which case adrenalin should be given. This is best administered subcutaneously. Overaction of the thymus gland is shown most decisively by the appearance of symptoms of lymphatism, and should at once be met by the administration of small and gradually increasing doses of thyreoid extract, by the application of the X-rays to the manubrium sterni, by reduction of carbohydrates and by an increase in proteins. Sometimes backward development of the sex organs is the most conspicuous feature, and in these cases marked improvement often results from the giving of thyreoid extract, even in cases in which there is no reason to suppose that the thyreoid gland is the first or chief offender. Infantilism is sometimes associated with signs of pancreatic incompetence, and is markedly improved by the use of the pancreatic extracts. Herter has described a similar form of infantilism in which he believes the defect of development resulted from the absorption of toxins from a too-flourishing intestinal flora. He has in these cases obtained good but variable results by careful dieting and by general hygienic supervision.

Generally speaking any case of infantilism is capable of improvement so long as ossification of the long bones is incomplete. It is, therefore, advisable that an X-ray examination of the state of the epiphyses should be made before beginning treatment, and that another examination should be made if the progress is not satisfactory.

Infantilism which has no perceptible cause (Ateleiosis) has hitherto met with no effective treatment. Nevertheless thyreoid extract should invariably be tried in those cases in which the symptoms are suggestive of thyreoid inadequacy and hypophyseal extract in those with obesity. Possibly the use of the latter remedy in larger doses than have hitherto been given may prove more effective. Apparently it is not possible to give an overdose of hypophysis by the mouth.

Senilism.—Morbid prematurity of the declining stages of development, like infantilism, may be the result of syphilis, of alcohol or of any severe or persistent intoxication. It may also be due to prolonged hardship, to excessive toil or worry, or indeed to any of the causes of premature old age if inordinately prolonged or carried to an extreme degree. Evidently, therefore, the prevention or treatment of senilism is identical with the prevention or treatment of old age. One need only add that no reliance whatever must be placed upon sour milk or upon any bactericidal or operative treatment directed to any part of the intestinal tract, and that temperance is as conducive to old age as the liberal use of food is conducive to vigorous youth and maturity.

Of that sensational and bizarre form of senilism which comes on without apparent cause and is termed Progeria, little can be said in regard to treatment, for nothing has hitherto seemed to be of any avail in arresting the inevitable progress of the disease from its onset in babyhood to its termination in premature senile decrepitude in youth.

H. G.

TREATMENT OF DISEASES OF THE BONES AND JOINTS

OSTEOMALACIA, ACHONDROPLASIA, HYPERTROPHIC PULMONARY OSTEO-ARTHROPATHY AND OSTEITIS DEFORMANS

It must be insisted on that all these are merely names for but little understood conditions in which the bones of adults become soft and yielding so that they very readily bend or break. We are familiar with the museum appearances of the bones, and we know other facts about them—for example: (1) That in the extreme condition known as osteomalacia, where the lower part of the skeleton and more especially the pelvis becomes like putty, pregnancy is the rule; (2) that achondroplasia is most certainly a disease which arrests the growth of the epiphyseal cartilages once they have become active; (3) that osteo-arthropathy is associated with wasting pulmonary disease, frequently tubercle; (4) that osteitis deformans is frequently associated with new growths of the bone and is attended with overgrowth of bone in some parts, associated with weakness in others.

Besides these facts we must not lose sight of a medley of other allied conditions, as, for example—

Von Recklinghausen's Disease, a fibrous degeneration of a bone—or bones—of unknown causation although readily diagnosed by skiagraphs.

Neurotrophic atrophy of bone observed in

anterior poliomyelitis, tabes, syringomyelia, epilepsy.

Fragilitas Ossium—a mere name to a symptom; including probably widely different conditions.

For all these strange and bizarre alterations in the adult or growing skeleton there must be a cause, and until that cause is recognised and placed on a sure foundation treatment is entirely empirical.

In general terms we may speak of terminating the pregnancy in osteomalacia—a confession of complete ignorance, of rest, fresh air, calcium salts, cod-liver oil, organic phosphorus compounds, etc.

I would, however, suggest that in some way all these diseases have a common origin, that is, some defective metabolism or retrogressive changes or atrophy in the anterior lobe of the hypophysis cerebri (pituitary gland); such a suggestion is by no means devoid of evidence to support it. We recognise that growth of much of the body as well as the metabolism is controlled by a complex arrangement in which the nervous system takes a share and which largely depends, in some cases, on various forms of internal secretion, as, for example, of the sex glands. What more natural than to believe that such an important part of the body as the skeletal structures own some similar control.

It is well recognised that the anterior and posterior lobes of the hypophysis cerebri are widely different in origin and in functions, and that "the anterior lobe is related to the general growth of the body, and especially of the skeleton, whilst the posterior lobe, which includes the pars intermedia, probably serves to promote the contractility and increase the tone of plain muscular tissue generally, as well as of the heart, and to excite the activity of certain glands, viz. the kidney and mammary glands" (Schäfer).

Experimental evidence also is not entirely wanting, for—

1. Ascoli and Legnani, in their records of experimental hypophysectomies, mention the occurrence, not only of undergrowths of bone, but of spontaneous fractures.

2. H. G. Turney, *Neurology* (March 12, 1913), reports a case of spontaneous fracture of the sternum associated with pituitary degeneration; a similar case has been reported by Langdon Brown.

3. Erdheim and Stumm describe enlargement of the hypophysis cerebri in pregnancy, chiefly due to the presence of finely granular cells in the anterior lobe of the gland, widely differing from the natural cells, and *in some cases almost taking their place completely.*

Clinical evidence is sparse.

A case of osteomalacia has been reported where a perfect cure was effected by the administration of hypophyseal extract.

The author of the present article has given fresh anterior lobe or preparations of the mixed gland (chiefly posterior lobe) in five cases with marked success in every case. Two of these were clear cases of Von Recklinghausen's disease, with failure of union of fractures—in both cases despite repeated surgical interference. In both cases, on the administration of hypophyseal extract the fractures united and there was no further trouble. A like satisfactory result was obtained in three cases of so-called "fragilitas ossium." These cases will be published later.

With regard to treatment, it must be remembered that these are only tentative suggestions. To the writer's knowledge no observations have been made post mortem on the state of the anterior lobe of the hypophysis in such cases—and skiagraphy in the few cases here noted has given no definite result; such rare cases may, however, provide an infinitely rich field for research, and it may well be that much more common skeletal defects may owe their origin to the same source.

It would appear that there is little danger of overdosage. The whole anterior lobe of a fresh *lamb's* hypophysis has been given three or even four times in the week.

The anterior lobe may be obtained in a dry condition from both Messrs. Burroughs Wellcome and Parke Davis, but the very great expense of the preparation is a serious bar to its continuous use.

Now that the posterior lobe is in such frequent use it should not be difficult to obtain the anterior lobe at a reasonable cost.
